

The Laspeyres-Paradox: Tax Overshifting in 19th Century Prussia

*Mark Spoerer**

This version: 28 March 2006

Abstract

Following the seminal work of late 19th century economist Etienne Laspeyres we analyse the incidence of the Prussian milling and butchery tax shortly before its repeal in 1875. A comparison of flour prices in cities which levied this tax with cities which did not reveals unusually strong tax overshifting. Modern theories which explain overshifting of a specific tax argue with quality improvements or imperfect competition fail in this case. Instead, we find that it was large surplus costs induced by tax collection and monitoring that made the milling process so costly and caused unusually large excess burdens. The reason why the tax remained nevertheless basically unchanged for over half a century is that the urban bourgeoisie successfully prevented its repeal because the alternative would have been the introduction of municipal direct taxes (rent-seeking behaviour).

I. Introduction

In November 1863, Ferdinand Lassalle, one of the founding fathers of the German Socialist Party, gave a public speech in which he criticized the Prussian tax system for its regressive distributional effects. Police arrested him right on the spot and he was charged of high treason. The public prosecutor justified his action on Lassalle's arguments on the incidence of indirect taxes which the prosecutor regarded as false and which he interpreted as sedition.

What did Lassalle say? Indirect taxes, he argued, lay especially heavy on the common people because the tax burden was fully shifted from the producers, who had to pay them formally, to their customers. As the propensity to consume was negatively correlated with income, the impact of indirect taxes, and above all the notorious Prussian milling and butchery tax, was regressive. Most contemporary economists, though critical of Lassalle's political aims, agreed with his analysis, so that the case against Lassalle had to be abandoned. Even today it is commonly assumed that the burden of indirect taxes is shifted—this is precisely one of the reasons why they are called "indirect".

Despite its obvious importance for the assessment of tax and redistribution policies, the analysis of the economic burden of taxation is still a very intricate issue in modern economics. On the theoretical side, there is a vast and very sophisticated literature that builds on Arnold Harberger's general equilibrium approach to incidence analysis. Empirical economists, however, have found many obstacles to correctly measure the tax burden and mostly stick to the partial analysis approach which is still quite difficult to perform.¹ Economic historians have only very rarely and remotely touched the issue.² In 1978, a short debate evolved between Peter Mathias and Patrick O'Brien on the one hand and Donald McCloskey on the other. The former analysed the impact of taxation on economic growth in Britain and France and acted on the usual assumption that the burden of indirect taxes was shifted whereas that of direct taxes was not. This provoked McCloskey's comment who argued that the incidence should be measured rather than assumed. Mathias and O'Brien responded that there were no data to elaborate on this issue

Triplett (eds.), *Fifty Years of Economic Measurement: The Jubilee of the Conference on Research in Income and Wealth*, Chicago: University of Chicago Press, pp. 343-408; John Creedy (1998), *Measuring Welfare Changes and Tax Burdens*, Cheltenham: Elgar, chs. 7, 8 and 11; Don Fullerton and Gilbert E. Metcalf (2002), "Tax incidence", in Alan J. Auerbach and Martin Feldstein (eds.), *Handbook of Public Economics*, vol. IV, Amsterdam et al.: Elsevier, pp. 1787-1872, here pp. 1817-1823.

² We could not find a single study published in English or German that analyses tax incidence historically. Jonathan B. Pritchett (1989), "The Burden of Negro Schooling: Tax Incidence and Racial Redistribution in Postbellum North Carolina", *Journal of Economic History*, 39, pp. 966-973, merely assumes a value for the incidence, like Mathias and O'Brien (see next footnote).

and that the "burden of proof" lay on McCloskey.³ Though Rolf Dumke and Eckart Schremmer soon joined McCloskey in pleading for a historical analysis of tax incidence, the issue has not been taken up by economic historians so far.⁴

For a start, the incidence of the Prussian milling and butchery tax is worth a closer look. As this tax was much disputed in Prussia, there is a comparably large literature on it. Moreover, it had a certain feature that is conducive to empirical analysis: it was levied just in a part of the Prussian cities, so that the others may serve as a natural control group.

The milling and butchery tax was introduced with the tax reform of 1820 when the Prussian state levied the so-called class tax on taxpayers in the countryside and those in most small cities. In most large cities the milling and butchery tax, a specific (or excise, i.e., not *ad valorem*) tax, was levied instead. While both taxes were state taxes, the cities were granted the right to add municipal surtaxes on either the class tax or the milling and butchery tax.

Nearly a decade after the Lassalle affair, the tax was repealed. Having lost its political explosiveness, it found the interest of the freshly tenured German economist Etienne Laspeyres, today well-known to economists for his price index formula. In 1877 and 1901, he published two articles in which he analysed the incidence of the Prussian milling and butchery tax. Laspeyres was not so much interested in the tax in itself but saw it as a useful example to analyze the incidence of tariffs, an issue intensely debated among German economists and politicians (Germany reintroduced protectionist tariffs in 1879). The fact that the milling and butchery tax had been levied only in a part of the Prussian cities allowed him to compare the prices of flour and meat in cities with the tax and in cities without (i.e., in which the class tax was levied instead). His empirical results seemed paradoxical. In line with the prevailing economic thinking of the time he had expected that the burden of the tax would be shifted fully or nearly fully from the producers to the consumers, that is in the area of 100 per cent or below. Yet, whereas he found that this was indeed the case for the butchery tax, the shifting of the milling tax was around 120 per cent in the case of wheat flour and around 200 per cent in the case of rye flour.

In his 1877 article, Laspeyres tried to explain why the prices of flour were much higher than one would expect. However, his economic arguments were not convincing and rather showed a

certain helplessness. In the 1901 article, he restrained himself from any economic explanation. In a way, the analysis he performed in the second article was what would be called a few decades later 'measurement without theory'.⁵ His German colleagues mainly ignored his results or used them as an argument to show that it was anyway useless trying to determine tax incidence empirically. Although Laspeyres' analysis is probably the earliest and certainly the most detailed early attempt to specify the incidence of a tax empirically, this piece of his oeuvre has fallen into oblivion.⁶

After World War II, discussions on the distributional effects of taxation raised interest in the incidence issue. An increasing number of empirical studies found that certain specific taxes were shifted by more than 100 per cent. Soon, the phenomenon was named overshifting. We will discuss recent theoretical contributions to explain overshifting in the next section. In the third section, we return to the Prussian milling and butchery tax and check whether we can reproduce Laspeyres' empirical findings. This will be the case and so we analyse in the fourth section whether modern approaches are able to explain Laspeyres' paradox. They are not and we will argue that the observed overshifting was a result of extraordinary high tax collection and monitoring costs. In the concluding section we will discuss why Prussia stucked for over half a century to a tax that weighed unusually heavy on producers, consumers and even the state.

II. Overshifting in Theory

It was only after World War II when economists took an interest in empirically analyzing tax incidence again. Occasionally, these analyses produced findings similar to those of Laspeyres' three quarters of a century before. Among them was, for example, William Niskanen who analysed the demand of alcoholic beverages.⁷

These results did not seem compatible with the theory at the time. In general, the opportunity to shift the burden of a producer tax to the consumer depends on the elasticities of demand and supply. In a partial analytic framework with a specific production tax the share of the tax burden borne by the consumers is

⁵ Tjalling C. Koopmans (1947), "Measurement without Theory", *Review of Economic Statistics*, 29, pp. 161-172.

⁶ Even Edwin Seligman, who was strongly influenced by German public economists, did not discuss Laspeyres' articles on tax incidence, although he was aware of the (in Germany hardly ever quoted) 1877 article; Edwin Seligman (1910), *The Shifting and Incidence of Taxation*, 3rd edn., New York: Columbia University Press, p. 372. In the second edition of 1899, there is no reference made to this part of Laspeyres' work, see p. 300.

⁷ William A. Niskanen (1963), *The Demand for Alcoholic Beverages*, Ph.D. diss. Chicago, pp. 54f. See for an overview of early studies that found overshifting: James M. Poterba (1996), "Retail Price Reactions to Changes in State and Local Sales Taxes", *National Tax Journal*, 49, pp. 165-176.

$$(1) \quad dp / dt = \varepsilon / (\varepsilon - \eta),$$

where p denotes the price, t the tax rate, ε the price elasticity of supply and η the price elasticity of demand (usually, $\eta \leq 0$). Under the assumptions of elastic demand, competitive markets and an upward sloping supply curve, the producers can shift only a part of the tax burden to the consumers. If demand is totally inelastic or, following Ricardo, the supply curve is flat, the producers can pass the whole burden on to the consumers. As a result, the price without tax, p^* , rises to $p(t)$ after the tax is levied, and the following inequalities hold:

$$(2) \quad 0 \leq \Delta p(t) = p(t) - p^* \leq t \leftrightarrow 0 \leq \Delta p(t)/t \leq 1.$$

Hence, under the usual assumptions the shifting cannot exceed 100 per cent of the tax amount, and there is no room for overshifting in the partial analytic framework.⁸

The first theoretical explanation for overshifting was formulated by Yoram Barzel in 1976. He showed that levying a specific tax may lead to an increase of the taxed product's quality.⁹ The intuition is that if a producer of, e.g., cigarettes has to pay a tax of 10 cents per cigarette regardless of its value, he will have an incentive to improve the quality of the tobacco or to produce longer cigarettes so that he can dilute the tax burden. Due to the better quality of his product, he may be able to increase the price by more than 10 cents. Barzel's explanation is regarded as the first explanation for overshifting. In our view, however, this is not quite the case as Barzel looked at two different products: one before taxation, and an improved one afterwards. Hence the *ceteris paribus* condition is violated.

Further and more convincing explanations came up in the 1980s with the boom of the industrial organization literature that allowed for imperfect competition. In an unpublished but often quoted paper, Jesús Seade showed that in the case of oligopolistic competition a specific tax may lead to overshifting. The intuition behind his argument and others that followed soon is as follows. The imposition of the tax will typically increase costs and thus the price which leads to a reduction of demand and thus the equilibrium number of firms. This reduction leads to an increase of market power (i.e., the opportunity to sell above marginal costs) for the remaining firms who will increase prices. If the price elasticity of demand is sufficiently inelastic, this price increase will exceed the tax amount, and overshifting will occur.¹⁰ Empirical work on the US

retail trade that makes use of precisely the same feature as Laspeyres, that is of the fact that different US cities levy different local sales tax rates, does indeed find overshifting, especially for non-durable consumer goods.¹¹ This strand of the literature also discovered that it has an eminent ancestor. As early as in 1838, it was Augustin Cournot who, discussing the effect of a specific tax on a monopoly product, had deduced mathematically that in this case the gross price of the product may increase by more than the tax amount.¹²

III. The Incidence of the Prussian Milling and Butchery Tax

In this section and the following, we address two questions. First, if we control for other factors that might affect Prussian flour and meat prices, are we able to reproduce Laspeyres' findings? Second, if so, are the approaches in the modern literature suited to explain what Laspeyres found paradoxical?

The Prussian milling and butchery tax was introduced in 1820. The criteria on which the central government in Berlin decided whether a city should levy the milling and butchery tax or the class tax were city size and, in respect to guarding the tax line, topographical characteristics. A peculiar feature was that the tax was levied only in part of the Prussian cities. In the other, often (but not always) small cities and the remaining rural areas, the Prussian state levied the class tax, which was a hybrid of a poll tax and a primitive income tax. The milling and butchery tax was not introduced in Westphalia and in the new northwest German territories Prussia acquired in 1866 (except Frankfurt on Main, where it was introduced).

[Figure 1 about here]

Both taxes, but especially the milling and butchery tax, faced strong criticism. When contemporary economists discussed tax reforms in Prussia, many criticized the milling and butchery tax for three reasons. First, it was obviously an unsystematic feature of the tax system to have the rural residents and part of the urban residents pay the (direct) class tax and the other part of the urban residents pay the (indirect) milling and butchery tax. This divided the tax system between the countryside and most cities. Second, the milling and butchery tax required a tax line that had to be drawn around the affected cities. Inside this line, which was guarded and thus costly, milling grain and slaughtering cattle was subject to permission and monitoring of the

II, pp. 484, 487. Cf. Delipalla and Keen (1992), p. 356.

local tax authorities. Tax line and supervision hampered trade. An unwelcome though not surprising side-effect was widespread smuggling, mainly of flour. Third, economists and practitioners widely assumed that at least a part of the tax burden was shifted to the consumers via an increase of flour prices and thus of bread prices. After the publication of what became known as Engel's Law in 1857, the regressive consequences were obvious.¹³ In addition, even in cities of comparable size and wealth the milling and butchery tax load per capita was about twice as high as the class tax load per capita. These deficiencies evoked criticism at a time when the social question gained increasing attention.

As a consequence, the history of the milling and butchery tax is full of attempts to reform or to repeal it. The protests peaked in the years of famine 1846-7 and in the 1860s, when the social question came on the political agenda—see the detention of Lassalle. Only when the Prussian state finances were in unusual good shape was the tax repealed in 1873 (effective 1st January 1875).

Laspeyres devoted two articles to the subject. The first was published in 1877 in an Austrian statistical journal and was based on 13,440 monthly prices. For the second he had generations of students compute price averages from millions of monthly observations supplied by the Prussian Statistical Bureau. Finally, he published his second article 1901 in the renowned *Finanz-Archiv*.¹⁴

In neither article did Laspeyres perform a cross-section analysis by directly comparing the prices of cities that levied the milling and butchery tax (henceforth "tax cities") with those that did not (henceforth "non-tax cities"). Instead he compared the difference of the price changes in the two groups of cities shortly before and after the repeal, that is he performed a panel analysis. The main difference between the two articles was that in the latter Laspeyres increased the number of observed products and cities.

His basic findings were nevertheless the same: full shifting or weak undershifting of the butchery tax in the meat markets, weak overshifting of the milling tax in the wheat flour market and strong overshifting in the rye flour market. After the repeal of the tax, the price differences vanished immediately. We reproduce his main results in Table 1.

[Table 1 about here]

¹³ Ernst Engel (1857), "Die vorherrschenden Gewerbebezüge in den Gerichtsämtern mit Beziehung auf die Productions- und Consumtionsverhältnisse des Königreichs Sachsen", *Zeitschrift des sächsischen Statistischen Bureaus*, 3, pp. 129-182, here pp. 169-172.

¹⁴ Etienne Laspeyres (1877), "Statistische Untersuchungen über den Einfluss einer Steueraufhebung auf die Preise der bisher besteuerten Producte", *Statistische Monatschrift*, 3, pp. 497-514, 545-555; idem (1901), "Statist. Untersuchungen zur Frage der Steuerüberwälzung, geführt an der Geschichte der preussischen Mahl- und Schlachtsteuer. Nach gedruckten und ungedruckten Quellen", *Finanz-Archiv*, 18, pp. 46-282.

As Laspeyres used a larger sample and a slightly refined analysis in his 1901 article, we refer to the right part of Table 1 (cols. v to viii). Column (v) shows the absolute amount of the tax in *Pfennig* per kilogram, and column (vi) compares this to the average price in the tax cities. As we can see, wheat flour was taxed strongest relative to its value. In column (vii), Laspeyres compares the difference of the price changes between non-tax cities and tax cities in 1874 and 1875, when the tax became ineffective. In tax cities the changes of flour and meat prices were much stronger than in non-tax cities. The pork prices, e.g., were in line with the predictions of the theory as the average price decrease between 1874 and 1875 was 8.3 *Pfennig* larger in tax cities than in non-tax cities. This difference was slightly below the amount of the tax (9.0 *Pfennig*), which thus had been nearly fully shifted in 1874, more precisely by 92 per cent (col. viii = col. vi / col. vii). The shifting of the tax on wheat flour was a bit outside the expected range ($1.2 > \max [0.0; 1.0]$) and could possibly be attributed to measurement error, but that of rye flour was disturbing. How could a tax of 1.67 *Pfennig* per kilogram of rye flour have caused a price difference of 3.1 *Pfennig* between tax cities and non-tax cities? Laspeyres performed an impressive series of sensitivity analyses in order to detect pseudo-correlations, but to no effect.

Now, are we able to reproduce Laspeyres' results? While he performed a kind of panel analysis (differences in price changes between tax cities and non-tax cities before and after the repeal of the tax 1874-75) we confine ourselves to a cross-section analysis (differences in price levels between tax and non-tax cities) which should essentially lead to the same results.

We rely on the same data source for prices as he did. The Prussian Statistical Office published monthly prices of food and other necessities since 1865 which, in 1873, covered 157 cities. Here we use the prices from July 1873 to June 1874. This allows a comparison with Laspeyres' data which are from January 1874 to December 1875 and avoids any anticipatory effects (hardly anybody would have postponed meat consumption for six months). We also collected prices for rye and wheat, the main inputs for the flour production. Local cattle prices, however, were not recorded by the statistical office. Table 2 summarizes the main descriptive characteristics of the price and tax data.

[Table 2 about here]

If we compare the average tax amount (col. vi) with the difference of the price means between tax cities and non-tax cities (col. iv – col. i) we can reproduce what Laspeyres found paradoxical, i.e. strong overshifting of the tax in the rye flour market, weak overshifting for wheat flour and undershifting for meat (e.g., rye flour: $38.15 - 35.11 = 3.04 > 1.90$, etc.).

One can nevertheless think of factors other than the tax that could explain the price differences. As the tax was more likely to be levied in large towns with (possibly) higher price

levels one could speculate that Laspeyres just measured a spurious correlation. Given the large differences between the advanced western parts and the backward East of Prussia, one could also think of regional idiosyncrasies that affected the output prices of flour and meat, such as wages and other input prices. E.g., the high mean of the beef prices in non-tax cities is driven by two Prussian cities adjacent to Hamburg, then the richest German city on per capita basis. Hence, when recalculating Laspeyres' results it may be sensible to control for these factors simultaneously.

The most important independent variable is the tax. While Laspeyres' approach was like using a dummy variable for the tax, we use actual tax rates in our regressions (except those in Tables 4 and 6). The actual tax rates include the state tax, which was uniform all over Prussia, and the municipal surtax which was in the range of 0 to 50 per cent of the state tax.¹⁵ For the production costs of rye flour and wheat flour we include grain prices and wages.

Nationwide wage data are difficult to find for pre-1900 Germany. The earliest source for Prussia are wages paid in the Prussian forest domains.¹⁶ These were, however, only recorded in retrospect by seemingly reluctant rangers and display an unusually large variance. Moreover, they are not available for many important industrial towns in the Western provinces. We rely on another source here which, to our knowledge, has been used very rarely so far. In 1883, Germany decreed a law that entitled workers to receive sickness benefits the amount of which were based on local minimum wages. Hence, all over Germany local commissions were charged with determining the minimum wage in their regions. Their work added up to a list of local minimum wages for several thousand cities, villages and even estates which was published by an official source since 1892.¹⁷ We were able to find a private source that assembled and published the first official data of the list, presumably for 1885 (or 1884).¹⁸ This date is ten years after the repeal of the milling and butchery tax and thus will by and large still reflect the regional wage differences of 1873-74. In so doing we also avoid a possible problem of endogeneity as contemporary authors assumed that the milling and butchery tax would enable workers to successfully demand higher wages in tax cities. Table 3 summarizes the descriptive statistics of the population and wage data.

[Table 3 about here]

A closer inspection reveals that the milling and butchery tax was mainly levied in the Eastern and less developed parts of Prussia (see also Figure 1). Taken together, we have the following data for the right hand side of the regression equations: the tax (with local surtaxes), grain prices, the wage level (in 1885) and city population (from the population census of 1871).

Before we proceed we have to check another possible problem of endogeneity, that is whether not only the flour, but the grain prices as well were affected by the tax, or, in other words, whether the tax was shifted backwards to the input producers, a case not analysed by Laspeyres. In Table 4 we show the results of regressions of the rye and wheat prices against a dummy which takes the value of 1 if the city levied the milling tax and against either wages (model I) or provincial dummies (model II).

[Table 4 about here]

Model I, which includes wages, suggests that rye and wheat prices were significantly lower in tax cities, 0.64 and 0.67 *Pfennig* per kilogram, respectively. If we compare the coefficients with the tax amounts (Table 1, col. v; note that we do not use logarithms for prices and taxes), this suggests a backshifting of 38 per cent in the case of rye and 10 per cent in the case of wheat. The difference seems to make sense, as a much larger share of the wheat production was traded internationally.

Turning to model II, which tries to capture regional idiosyncrasies by using dummy variables rather than by wages, we must conclude that the backshifting effect was numerically very low and insignificant. As the explanatory power of this model is much higher and as just taking wages is presumably not sufficient to control for regional idiosyncrasies, one might be tempted to attach more value to model II, which clearly rejects backshifting.

We nevertheless should keep in mind that there might be a problem of endogeneity. For this reason, we test in our recalculation of the Laspeyres-Paradox a third model for our regressions on the flour and meat prices which controls for endogeneity both of grain prices and wages.

[Table 5 about here]

For the interpretation it is important to keep in mind that the price and tax variables are not expressed in logarithms, which allows a straightforward interpretation of the coefficients.¹⁹ Our focus is on the coefficients of the tax variable which indicate the amount of tax shifting. For

¹⁹ This estimating strategy has the disadvantage that we run a higher risk of heteroscedasticity. Thus standard errors are corrected by the White procedure, if appropriate.

example, the coefficient of the first model for rye flour indicates that an increase of the tax by one *Pfennig* increases the price for rye flour by 1.93 *Pfennig*. Thus all three models signal strong overshifting in the rye flour market. For the wheat market, the results indicate weak overshifting, whereas the butchery tax was not fully shifted to the consumers. The coefficients for the production inputs make sense. An increase of the grain price of 1 *Pfennig* led to a similar increase of the flour price, and higher wages also went along with higher flour and meat prices. Hence, Laspeyres' results can be fully reproduced even if we control for more variables than he could, especially the large structural differences between the various Prussian provinces.

IV. What Caused Overshifting?

How can we explain our findings (and those of Laspeyres)? If we ignore the possibility of backshifting in the meat market (for which we lack cattle price data), the relative differences in forward shifting—meat prices undershifted, wheat flour prices weakly overshifted and rye flour prices strongly overshifted—may be due to different price elasticities of demand. Yet this does not explain the unexpectedly high levels of tax shifting in the flour market.

Before we turn to the theoretical approaches introduced in section II, we discuss a phenomenon often mentioned in the contemporary literature: smuggling. Smuggling livestock or meat into the cities was difficult. What people did smuggle on sizeable scale was flour. The authorities complained that smuggling flour was a kind of common sport of the urban poor. An interesting feature is that, according to the Prussian finance minister in an aide-memoire for a parliamentary hearing, no smuggler would ever smuggle rye flour, all those who were captured had the more expensive wheat flour with them.²⁰ This must have put downward pressure on the prices of wheat flour, and, to a lesser extent, of rye flour as well, because it was a partial substitute. Obviously, this argument works in the opposite direction, as we find for flour overshifting, not undershifting. If any, this may, along with the elasticity argument, help to explain the difference in overshifting between wheat and rye flour.

It is interesting to note that when the smugglers decided to focus on wheat flour they followed precisely the rationale that is behind the quality argument of Barzel. Being caught with a given quantity of contraband would lead to a penalty regardless of its value. Thus the smugglers focused on wheat flour which was, relative to the price, much higher taxed than either rye flour or meat (Table 1, col. vi).

²⁰ Von Duesberg (1847), "Denkschrift betreffend die Aufhebung der Mahl- und Schlachtsteuer, die Beschränkung der Klassensteuer und die Erhebung einer Einkommensteuer", in Eduard Bleich (ed.), *Der Erste Vereinigte Landtag in Berlin 1847*, vol I, Berlin 1847, S. 40-64, here p. 60.

The same reasoning held for the legal trade in livestock and meat as well. There is convincing anecdotal evidence that the quality of meat was definitely better in tax cities than in non-tax cities.²¹ The reason given by the contemporary literature mirrors exactly Barzel's argument. As the butchery tax was levied per piece of cattle, there was an incentive to bring high-quality livestock in the cities. This explanation, however, also works in the wrong direction, as an improvement of quality would explain overshifting in the meat market, not, as observed, undershifting. In contrast, there is not a single hint in the contemporary literature that the flour or the bread consumed in tax cities was of superior (or inferior) quality.

What about the second argument of the theoretical literature, that is imperfect competition? It should be clear that any argument that rests on imperfect competition must explain why there were barriers to competition in the tax cities but not in the non-tax cities. In this respect it is interesting to note that the milling and butchery tax law of 1820 stipulated that the establishment of grain mills was subject to government approval.²² Thus one can speculate that the local authorities made restrictive use of this rule either deliberately to protect existing businesses or unintentionally, perhaps because they constantly underestimated the pace of city growth.

How can we test imperfect competition? Profit data are not available, but data on the number of businesses and their employees are. This may give clues on whether there was business concentration among the bakeries and butcheries in tax cities. The only business census that is close to our year of investigation, 1873-74, dates from the first of December 1875, that is eleven months after the milling and butchery tax became ineffective. It is nevertheless plausible that the market structure that had developed under the tax regime was still existent eleven months after the repeal of the tax. Thus it might be worthwhile to analyse this data set of 54 Prussian cities.

[Table 6 about here]

If we control for population, wages and regional variation, the typical bakery in a (former) tax city occupied on average 0.6 employees more than in non-tax cities, while the overall average was three employees (including the owner). Moreover, the density of bakeries was (weakly) significantly lower as well. In contrast, the coefficients for butcheries are close to zero and far from significant on conventional levels. Hence we find evidence that the tax regime caused concentration in the bakery business, but not in the butchery business.

²¹ For references, see Mark Spoerer (2004), *Steuerlast, Steuerinzidenz und Steuervettbewerb. Verteilungswirkungen der Besteuerung in Preußen und Württemberg (1815-1913)*, Berlin: Akademie, p. 156.

²² §7b, see Ernst Engel (1868), "Die Ergebnisse der Classensteuer, der classificirten Einkommensteuer und der Mahl- und Schlachtsteuer im Preussischen Staate", *ibid.*, 8, pp. 25-84, here, p. 32.

However, as the industrial organization literature stresses, concentration does not necessarily imply market power. And there is ample anecdotal evidence that not only the butchers but the bakers alike vividly rejected the tax.²³ Hence the concentration was very probably not a result of a tax-induced increase of market power. We thus have to look for another argument that is able to reconcile the finding that the bakery business experienced overshifting and concentration in the tax cities (but no concentration in non-tax cities), whereas the butchery business was not able to shift the tax burden to the consumers and was not concentrated.

A more detailed look at the contemporary discussion offers an alternative interpretation. Is it conceivable that tax collection and monitoring incurred considerable surplus costs in the bakery business that increased average costs and made the minimum optimal scale of bakeries increase? If this was the case this would explain not only why there was overshifting in the flour market (Table 5) only but also why there were less and larger bakeries in tax cities (Table 6).

There is some evidence on the costs. The milling and butchery tax was extremely expensive to collect. The state had to sustain the tax line around the tax cities. Thus the costs did not only cover the tax administration, but the maintenance of the city walls and gates as well, which had been preserved only for the purpose of collecting the the milling and butchery tax. The ratio of collection costs to gross revenues was on average between 15 to 20 per cent, which was much higher than for every other Prussian tax. In small cities, this ratio would even increase to 40 per cent.²⁴

These costs were borne by the state. For our problem it is more interesting to see whether there were tax-induced surplus costs imposed on bakers or butchers. Controlling the butchers did not require a sophisticated procedure, as livestock was difficult to hide. Every butcher had to keep books of his livestock which could be updated by the authorities only. Livestock that came into the city was added to his books, animals slaughtered under guidance of the authorities were subtracted. Any illegal import or slaughtering would have led to a mismatch of actual stock with the records in the books.

Whereas the quantity and quality of livestock was easily controlled, that of grain or flour was not. The controls were to avoid three illegal practices: smuggling grain or flour into the cities, importing high-taxed wheat (flour) declared as low-taxed non-wheat grain (flour) and clandestine

²³ See, e.g., F. Schemioneck (1863), *Die Mahl- und Schlachtsteuer in Berlin*, Berlin: Selbstverlag p. 3; *Denkschrift über die Mahlsteuer und ihre nachtheiligen Folgen für die weniger bemittelten Volksklassen, sowie insbesondere für das Bäckergerbe*. Hrsg. v. Vorstände der Bäcker-Corporation in Köln, Cologne: Bachem 1869; and especially Hans Teschemacher (1912), *Die Einkommensteuer und die Revolution in Preußen. Eine finanzwissenschaftliche und allgemeingeschichtliche Studie über das preußische Einkommensteuerprojekt von 1847*, Tübingen: Laupp, pp. 26f.

²⁴ Cf. *Verhandlungen des Hauses der Abgeordneten. Sammlung sämtlicher Drucksachen des Hauses der Abgeordneten*, vol. 225, Berlin 1870, pp. 665-671.

grain milling. For these reasons any incoming flour was taxed at the city gate, whereas the procedure was much more complicated with grain. Incoming grain was registered and thoroughly checked at the gate. The importing trader or baker had to specify the type of grain, number and weight of sacks, name and residence of the taxpayer, planned processing and mill. The importer would then receive a tax voucher which entitled him to have his load weighed. Only then was he allowed to proceed to the mill, where the milling process had to be constantly supervised by an official of the authorities. The millers were also subject to intense monitoring. Flour was to be stored only in specified rooms the access to which was strictly controlled. Grain traders, millers and bakers criticized most that they had to wait days or even weeks to get the grain milled. Storing it tied capital and risked that the produce rotted. On top of these indirect costs the tax authority forced the millers to pay the official supervisors' salaries.²⁵

Thus we can expect that the tax collection and monitoring process induced an increase both of fixed costs and variable costs. The supervisor's salary and the increase of grain storage capacity caused additional fixed (and/or step-variable) costs, while the bureaucratic procedures and the wastage due to the waiting time added to the variable costs. An increase of fixed costs and variable costs leads to higher average costs and thus prices. This has two effects. First, a higher price leads to a decrease in demand and sales which drives marginal firms out of the market. This effect was probably weak because of the low price elasticity of demand for bakery products. Second, and probably more important, is that the increase of fixed costs was apparently larger than that of variable costs and thus increased the minimum efficient scale.²⁶ This may explain why there were less and larger bakeries in tax cities.²⁷

To summarize, the Prussian milling tax incurred unusually large costs. The producers had to bear surplus costs which they put on the sales price. The consumers had to pay flour prices that were considerably higher than in non-tax cities and the state bore larger collection costs than with any other tax. The total welfare losses are visualized in Figure 2.

[Figure 2 about here]

²⁵ Schemoneick (1863), pp. 6, 16. See also Otto Wolff (1864), "Die Mahl- und Schlachtsteuer", *Vierteljahrsschrift für Volkswirtschaft, Politik und Kulturgeschichte*, 2, pp. 168-196, here 196; Max von Heckel (1893), "Schlacht- und Mahlsteuer", in *Handwörterbuch der Staatswissenschaften*, 1st edn., vol. V, Jena: Fischer, pp. 571-576.

²⁶ To see this, consider the following cost function: $C(x)=F + vx^n$ with total costs C , fixed costs F , variable costs v and quantity x . The exponent n is typically larger than unity. The minimum efficient scale x^* is where the marginal cost curve cuts the average cost curve, that is $C'(x)/x = C(x)/x$. After some transformations: $x^*=(F/(v(n-1)))^{1/n}$. Hence for an increase of x^* , $\Delta F/F > \Delta v/v$.

²⁷ The effect vanished after the repeal of the tax. In 1907, bakeries (and butcheries) were neither larger in former tax cities than in non-tax cities nor were they more concentrated, cf. *Gewerbliche Berufsstatistik, Abt. VI: Kleinere Verwaltungsbezirke; Preußen (Berufs- und Betriebszählung vom 12. Juni 1907)* (Statistik des Deutschen Reichs, n.s. vol. 218). Ed. by Kaiserliches Statistisches Amt, Berlin: Puttkammer & Mühlbrecht 1909. Data are available for all 54 cities of the 1875 sample. In none of the four regressions is the tax dummy significantly different from zero, not even on the 20 per cent confidence level.

In the common partial analytic framework the introduction of a specific production tax causes a shift of the supply curve from S_0 to S_1 by the tax amount t which produces a welfare loss of the triangle L_1 . The argument put forward here is that the milling tax imposed considerable indirect (storage, dwindling etc.) and direct (supervisors' wages) surplus costs Δc that increased the supply curve even further, from S_1 to S_2 , inducing a welfare loss of triangle L_2 . This also explains the Laspeyres-Paradox. While Laspeyres believed to measure $p_1 - p_0$ and wondered how this could exceed t , he really observed $p_2 - p_0$, which, given the low price elasticity of demand for grain and especially rye products, was larger than t .

V. Conclusion: The Political Economy of the Milling and Butchery Tax

This paper has shown that, while the French economist Augustin Cournot is the theoretical mastermind of today's literature on tax overshifting, the German economist Etienne Laspeyres should be seen as the empirical forebear. The shifting of the Prussian milling and butchery tax that he observed, however, cannot be explained by today's theoretical approaches. The reason must very probably be sought in considerable surplus costs that were induced by the still quite primitive means to monitor the tax collection process in 19th century Prussian cities.

One question, however, has so far remained unaddressed. If the Prussian milling and butchery tax caused high costs to producers, consumers and the state alike, why then was it in existence for more than half a century without any major change?

The answer lies in the distributional effects of the tax. The Prussian state levied the unpopular milling and butchery tax, monitored its collection in the cities and had to defend it against political attacks. Since 1848, a third of the revenues were left to the cities. On top of that the cities levied municipal surtaxes which cost them merely a small contribution to the state for his collection efforts.²⁸ These revenues formed the backbone of many cities' local finances.

[Table 7 about here]

Because of the regressive character of the tax, the urban poor contributed considerably to the local public revenues. For the wealthy, the relative burden of the milling and butchery tax was minimal. There was even tax-induced migration of the rich into the tax cities. If a rural resident was able to convince the tax office that he spent at least six months of the year in a city

²⁸ Friedrich G. Schimmelfennig (1840), *Die preussischen indirekten Steuern oder die auf Produktion, Fabrikation und Konsumtion ruhenden Abgaben im Innern der preussischen Staaten. Eine systematisch geordnete Zusammenstellung der darauf Bezug habenden Gesetze und Verordnungen bis zum Schlusse des Jahres 1835*, vol. II, Potsdam: Riegel, p. 50; A. Reinick (1863/64), "Resultate der Mahl- und Schlachtsteuer in der Periode von 1838 bis mit 1861. Eine finanzstatistische Abhandlung", *Zeitschrift des königlich preussischen statistischen Bureaus*, 3, pp. 217-235, 4, pp. 160-167, here p. 163.

that levied the milling and butchery tax, he was exempted from the class tax.²⁹ Had the milling and butchery tax been repealed, the cities would have had to find an alternative. This would inevitably have resulted in a direct tax that had to be borne by the wealthy much more than the indirect milling and butchery tax. These considerations were publicly discussed by contemporary politicians, journalists and academics.³⁰

It is thus not surprising that there was one group that was outspokenly in favor of this tax: the urban rich.³¹ They controlled most city councils and the Prussian Lower House and voted repeatedly and successfully against the repeal of the milling and butchery tax. Lobbying for a tax that was annoying for everyone (at the least because of the onerous controls at the city gates) and that was regarded as inefficient by many contemporary authors thus made nevertheless perfect sense for this group. In essence, lobbying for the maintaining of the milling and butchery tax was a result of rent-seeking behaviour. Insofar it was probably the milling and butchery tax that should have been called class tax as its incidence fell on the urban poor in a much more pronounced way than even the Socialist Ferdinand Lassalle had dared to claim.

	I	II	I	II
Tax [Pf/kg]	-0.64** [0.25]	-0.08 [0.22]	-0.67* [0.28]	-0.07 (0.25)
Wages (log) [Marks/day]	+0.70 [0.47]	-	+2.28*** [0.50]	-
Provincial dummies significant on 5%-level	-	7	-	8
Constant	20.94*** [0.28]	21.98*** [0.33]	25.99*** [0.30]	28.65*** (0.29)
Average price [Pf/kg]	21.01	21.01	26.77	26.77
Observations (cities)	148	148	144	144
Adj. R2	0.07	0.47	0.19	0.43
Prob(F)	0.00	0.00	0.00	0.00

Notes: OLS. Model II has 10 dummies for 11 Prussian provinces. Standard errors in parentheses [White-corrected in brackets]. *, **, *** significant on 5, 1, 0.1 per cent level, respectively. Testing for population (in logs) or including wages in model II does not have mentionable impact on the results.

Table 5: Impact Factors on Flour and Meat Prices in Prussian Cities, 1873-74

Product	Rye flour			Wheat flour			Pork	Beef
	Model I	Model II	Model III	Model I	Model II	Model III	Model II	Model II
Tax [Pf/kg]	1.93*** [0.43]	1.77*** [0.52]	1.95*** [0.49]	1.09*** [0.10]	1.13*** [0.11]	1.17*** [0.12]	0.57** (0.21)	0.85** [0.29]
Price for rye or wheat [Pf/kg]	0.79** [0.28]	0.63 [0.46]	0.93* [0.43]	0.98* [0.41]	0.56 [0.37]	1.93** [0.72]	-	-
Wages (log) [Marks/day]	2.65 [1.68]	-	2.21 [2.08]	1.43 [1.70]	-	-1.27 [2.60]	11.46* (5.06)	20.60** [7.87]
Provincial dummies significant on 5%-level	-	5	-	-	1	-	9	4
Constant	17.01** [5.88]	24.97** [9.85]	14.18 [9.19]	20.54 [10.62]	32.56** [10.09]	-3.89 [18.56]	140.77*** (3.94)	126.92*** [5.87]
Average price [Pf/kg]	36.20	36.20	36.20	50.48	50.48	50.48	134.76	133.20
Observations (cities)	145	145	145	141	141	141	157	157
Adj. R2	0.15	0.25	0.15	0.34	0.51	0.28	0.44	0.45
Prob(F)	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00

Notes: Models I and II OLS, model III 2SLS. Model II has 10 dummies for 11 Prussian provinces. Model III uses the tax and ten regional dummies as instruments. Standard errors in parentheses [White-corrected in brackets]. *, **, *** significant on 5, 1, 0.1 per cent level, respectively. Testing for population (in logs) or dropping the wage variable in the flour regressions does not have mentionable impact on the results.
