May 2003

Presented as the Sargan lecture, Royal Economic Society, University of Warwick, April 2003. Denis Sargan developed much of the estimation theory that instrumental variables practitioners rely on today. For recent surveys of Sargan's contributions see Arellano (2002) and Phillips (2003). Special thanks go to Patricia Cortes and Francisco Gallego for outstanding research assistance and to Alberto Abadie, Victor Chernozhukov, and Guido Imbens for unusually helpful discussions and comments. The views expressed herein are those of the authors and not necessarily those of the National Bureau of Economic Research.

JEL No. C31, J12, J13

ABSTRACT

Instrumental Variables (IV) methods identify internally valid causal effects for individuals whose treatment status is manipulable by the instrument at hand. Inference for other populations requires some sort of homogeneity assumption. This paper outlines a theoretical framework that nests all possible homogeneity assumptions for a causal treatment-effects model with a binary instrument. The framework suggests strategies for using IV estimates for extrapolation, while making it clear that efforts to go from local average treatment effects (LATE) to population average treatment effects are inherently speculative. These ideas are illustrated in an application using sibling-sex composition to estimate the effect of child-bearing on economic and marital outcomes for mothers with two or more children. The application is motivated by welfare reform, which penalizes further childbearing by welfare mothers on the grounds that more children make continued poverty and welfare receipt more likely. The empirical results generally support the notion of reduced labor supply and increased poverty rates as a consequence of additional childbearing, but evidence on the impact of childbearing on marital stability and welfare use is more tenuous. Another interesting finding is that for the sample of teen mothers, LATE is essentially equal to the population average treatment effect.

Empirical economic research often focuses on causal inference for the purpose of prediction, yet it seems fair to say that most prediction involves a fair amount of guesswork. The relevance or “external validity” of a particular set of empirical results is always an open question. As Karl Pearson (1911, p. 157) observed in an early discussion of the use of correlation for prediction, “Everything in the universe occurs but once, there is no absolute sameness of repetition.” This practical difficulty notwithstanding, empirical research is almost always motivated by a belief that estimates for a particular context provide useful information about the likely effects of similar programs or events in the future. The investment of time and energy in often-discouraging empirical work reveals that most empiricists are willing to extrapolate.

The basis for extrapolation is a set of assumptions about the cross-sectional homogeneity or temporal stability of causal effects. As a graduate student, I learned about parameter stability as “the Lucas critique,” while my own teaching and research focuses on the identification possibilities for average causal effects in models with heterogeneous potential outcomes. Applied micro-econometricians devote considerable attention to the question of whether homogeneity and stability assumptions can be justified, and to the implications of heterogeneity for alternative parameter estimates. Sometimes – regrettably in my view – this sort of analysis comes at the expense of a rigorous examination of the internal validity of estimates, i.e., whether the estimates have a causal interpretation for the population under study. Clearly, however, even internally valid estimates are less interesting if they are completely local, i.e., have no predictive value for populations other than the directly affected group.

In this paper, I discuss the nature and consequences of homogeneity assumptions that facilitate the use of instrumental variables (IV) estimates for extrapolation.² To be precise, I am interested in the assumptions that link a Local Average Treatment Effect (LATE) tied to a particular instrument with the population Average Treatment Effect (ATE), which is not instrument-dependent. Implicitly, I have in mind

²Denis Sargan noted the difficulty of the core instrumental variables identification problem, i.e., identification in models with constant effects, in his seminal 1958 paper: “It is not easy to justify the basic assumptions concerning these errors, namely that they are independent of the instrumental variables.” (p. 396; quoted in Arellano, 2002).

prediction for populations defined by covariates. I focus on ATE because it answers the question: “If we were to treat individuals with characteristics X , what would the likely change in outcomes be”? This allows me to sidestep variability due to changes in the process determining treatment status. Average treatment effects are theoretically more stable than effects on the treated, since the latter depend on who gets treated as well as the distribution of potential outcomes.

IV estimates are of special interest in this context both because of their growing importance in empirical work (see, e.g., Moffitt, 1999), and because their *ex ante* generality is limited in a precise way by a number of well-known theoretical results. Except in special cases like constant treatment effects and certain types of randomized trials, the standard IV assumptions of exclusion and independence – analogous to the notion that the instrument induces a good experiment for the effect of interest – are not sufficient to capture the expected causal effect on a randomly selected individual or even in the population subject to treatment. Rather, basic IV assumptions identify causal effects on “compliers,” defined as the subpopulation of treated individuals whose treatment status can be influenced by the instrument. Although this limitation is unsurprising, the nature and plausibility of assumptions under which IV estimates have broader predictive power are worth exploring.

The next two sections develop a theoretical framework linking alternative causal parameters to population subgroups defined by their response to an instrument. These ideas are then applied to the *same sex* instrument, used by Angrist and Evans (1998) to estimate the effects of childbearing on labor supply. This instrument arises from the fact that some parents prefer a mixed sibling sex composition. The substantive inquiry in this case is motivated by American welfare reform, which penalizes further childbearing by women receiving public assistance on the grounds that increases in family size make continued poverty and welfare receipt more likely. I therefore look at effects on marital status, poverty status, and welfare use, as well as labor supply. Estimates of ATE for the effects of childbearing are generally smaller than estimates of LATE. As often seems to be the case with analyses by subgroups,

however, the ability to make sharp distinctions between alternative average effects is limited. On the other hand, estimates using the framework outlined here suggest that for teen mothers, LATE is virtually identical to the population average treatment effect.

1. Causality and Potential Outcomes in Research on Childbearing

The effects of children on marital stability have long been of interest to social scientists and are of more than academic interest to many married couples. Previous research (e.g., Becker, Lanes, and Michael, 1977; Cherlin, 1977; Heaton, 1990 and Waite and Lillard, 1991) suggests the presence of young children increases marital stability, although many authors acknowledge serious selection problems. A related issue is the connection between childbearing and women's standard of living. A large literature looks at the effect of teen childbearing on mothers' schooling, earnings, and welfare status, sometimes using instrumental variables (e.g., Bronars and Grogger, 1994). Interest in this question can be motivated by welfare reform, which include "family caps" in many U.S. states. Family caps reduce or eliminate benefits paid for children born to welfare recipients, on the theory that further childbearing by welfare mothers increases the likelihood they will stay poor and therefore continue to receive benefits.³

Are children the glue that holds couples together or a burden that accelerates a fragile family's collapse? Does childbearing further impoverish poor women? Implicit in these questions is the notion of potential outcomes, i.e., a contrast in circumstances with and without childbearing, for a given family. To represent this idea formally, let D_i be an indicator for women with more than two children in a sample of women with at least two children. Because D_i is binary, I will refer to it as a "treatment," even though family size is not determined directly by a program or policy. Let Y_{1i} be a woman's circumstances if $D_i=1$, and let Y_{0i} be her circumstances otherwise. We imagine both of these potential outcomes are well-defined

³See Maynard, *et al* (1998) for more on the motivation for family caps. The possibility of a link between childbearing and poverty notwithstanding, there is little evidence that family caps actually affect fertility behavior. See, e.g., Grogger and Bronars (2001), Blank (2002) or Kearney (2002).

for everyone, though only one is ever observed for each woman.

For both practical and substantive reasons, I focus here on fertility consequences defined with reference to the transition from two to more than two children. On the practical side, instruments based on sibling sex composition are available for this fertility increment. Angrist and Evans (1998) used parents preferences for a mixed sibling sex composition to estimate the labor supply consequences of childbearing. On the substantive side, post-war reductions in marital fertility have been concentrated in the 2-3 child range (see, e.g., Westoff, Potter, and Sagi, 1963). While almost all couples want at least one child, the decision to have a third child may be due in part to a sense of whether this is good for long-term marital stability or, more generally, the economic welfare of the family. Finally, the population of welfare mothers in 1990 had an average of about 2.3 children and a median of 2 children.

Since both Y_{1i} and Y_{0i} are never both observed for the same woman, research on causal effects tries to capture the average difference in potential outcomes for different subpopulations. For example, we may be interested in $E[Y_{1i} - Y_{0i} | D_i=1]$, which is the effect on women who have a third child. Note that $E[Y_{1i} | D_i=1]$ is an observed quantity, so estimating $E[Y_{1i} - Y_{0i} | D_i=1]$ is equivalent to estimating the counter-factual average, $E[Y_{0i} | D_i=1]$. Alternately, we may be interested in the unconditional average treatment effect (ATE), $E[Y_{1i} - Y_{0i}]$, which can be used to make predictive statements about the impact of childbearing on a randomly chosen woman (or a woman with a particular set of characteristics if the analysis conditions on covariates). Estimation of ATE is equivalent to estimation of both counterfactual averages, $E[Y_{0i} | D_i=1]$ and $E[Y_{1i} | D_i=0]$.

Causal parameters are easy to describe but hard to measure. The observed difference in outcomes between those with $D_i=1$ and $D_i=0$ equals $E[Y_{1i} - Y_{0i} | D_i=1]$ plus a bias term:

$$\begin{aligned} E[Y_{1i} | D_i=1] - E[Y_{0i} | D_i=1] &= E[Y_{1i} | D_i=1] - E[Y_{0i} | D_i=0] \\ &= E[Y_{1i} - Y_{0i} | D_i=1] + \{E[Y_{0i} | D_i=1] - E[Y_{0i} | D_i=0]\}. \end{aligned} \tag{1}$$

The bias term disappears when childbearing is determined in a manner independent of a woman's potential outcomes. But this independence assumption seems unrealistic since childbearing decisions are made in light

of information about family circumstances and earnings potential.

Two sorts of strategies are typically used to estimate causal effects in the presence of possible omitted variables bias. One assumes that conditional on covariates, X_i , the regressor of interest, D_i , is independent of potential outcomes. Then any causal effect of interest can be estimated from weighted conditional-on- X comparisons. This is a strong assumption that seems most plausible when researchers have considerable prior information about the selection process. Alternately, we might try to find an instrumental variable which, perhaps after conditioning on covariates, is related to D_i but independent of potential outcomes. The instrument used here is a dummy variable indicating same-sex sibling pairs.

2. IV in context

IV estimates capture the effect of treatment on the treated for those whose treatment status can be changed by the instrument at hand. This idea is easiest to formalize using a notation for potential treatment assignments that parallels the notation for potential outcomes. In particular, let D_{0i} and D_{1i} denote potential treatment assignments indexed in relation to a binary instrument. Suppose, for example, D_i is determined by a latent-index assignment mechanism,

$$D_i = 1(\gamma_0 + \gamma_1 Z_i > \eta_i), \quad (2)$$

where Z_i is a binary instrument, and η_i is a random error independent of the instrument. Then the potential treatment assignments are $D_{0i} = 1[\gamma_0 > \eta_i]$ and $D_{1i} = 1[\gamma_0 + \gamma_1 > \eta_i]$, both of which are independent of Z_i . More generally, D_{0i} tells us what treatment i would receive if $Z_i=0$, and D_{1i} tells us what treatment i would receive if $Z_i=1$. Paralleling potential outcomes, only one potential assignment is ever observed for a particular individual.

The key assumptions supporting IV estimation are given below (for a model without covariates):

Independence. $\{Y_{0i}, Y_{1i}, D_{0i}, D_{1i}\} \perp\!\!\!\perp Z_i$.

First stage. $P[D_i=1 | Z_i=1] \neq P[D_i=1 | Z_i=0]$.

Monotonicity. Either $D_{1i} \geq D_{0i} \forall i$ or vice versa; without loss of generality, assume the former.

These assumptions capture the notion that the instrument is “as good as randomly assigned” (independence), affects the probability of treatment (first-stage), and affects everyone the same way (monotonicity). Imbens and Angrist [1994] show that together they imply:

$$\frac{E[Y_i | Z_i=1] - E[Y_i | Z_i=0]}{E[D_i | Z_i=1] - E[D_i | Z_i=0]} = E[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}].$$

The left-hand side of this expression is the population analog of Wald’s (1940) estimator for regression models with measurement error. The Local Average Treatment Effect (LATE) on the right hand side, $E[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}]$, is the effect of treatment on those whose treatment status is changed by the instrument, i.e., the population for which $D_{1i}=1$ and $D_{0i}=0$.⁴

Angrist, Imbens, and Rubin (1996) refer to people with $D_{1i} - D_{0i} = 1$ as the population of *compliers*. This terminology is motivated by an analogy to randomized trials where Z_i is a randomized offer of treatment and D_i is actual treatment status. Since $D_{1i} - D_{0i} = 1$ implies $D_i = Z_i$, compliers are those who comply with an experimenter’s intended treatment status. For compliers, the averages of Y_{1i} and Y_{0i} as well as the average difference are also identified. In particular, Abadie (2002) shows that

$$\frac{E[Y_i D_i | Z_i=1] - E[Y_i D_i | Z_i=0]}{E[D_i | Z_i=1] - E[D_i | Z_i=0]} = E[Y_{1i} | D_{1i} > D_{0i}] \quad (3a)$$

$$\frac{E[Y_i(1 - D_i) | Z_i=1] - E[Y_i(1 - D_i) | Z_i=0]}{E[(1 - D_i) | Z_i=1] - E[(1 - D_i) | Z_i=0]} = E[Y_{0i} | D_{1i} > D_{0i}]. \quad (3b)$$

⁴Proof of the LATE result: $E[Y_i | Z_i=1] = E[Y_{0i} + (Y_{1i} - Y_{0i})D_i | Z_i=1]$, which equals $E[Y_{0i} + (Y_{1i} - Y_{0i})D_{1i}]$ by independence. Likewise $E[Y_i | Z_i=0] = E[Y_{0i} + (Y_{1i} - Y_{0i})D_{0i}]$, so the Wald numerator is $E[(Y_{1i} - Y_{0i})(D_{1i} - D_{0i})]$. Monotonicity means $D_{1i} - D_{0i}$ equals one or zero, so $E[(Y_{1i} - Y_{0i})(D_{1i} - D_{0i})] = E[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}] P[D_{1i} > D_{0i}]$. A similar argument shows $E[D_i | Z_i=1] - E[D_i | Z_i=0] = E[D_{1i} - D_{0i}] = P[D_{1i} > D_{0i}]$.

The entire (marginal) distributions of Y_{1i} and Y_{0i} are similarly identified, a fact used by Abadie, Angrist, and Imbens (2002) to estimate the causal effect of treatment on the quantiles of potential outcomes.

An important result in the theory of causal effects is that when treatment is assigned by a mechanism like (2), population average treatment effects and the effect on the treated are not identified without assumptions beyond the 3 given above. This result appears in various forms; see, for example, Chamberlain (1986), Heckman (1990), and Angrist and Imbens (1991). The next section develops a framework that highlights the limits to identification and the role played by alternative homogeneity assumptions in efforts to go beyond LATE. The *Same sex* instrument offers an especially challenging proving ground for these ideas since at most 7% of women have an additional child in as a result of sex preferences. Causal effects on *same sex* compliers can therefore be quite far from overall average effects. Before turning to a general discussion of treatment effect heterogeneity, I briefly explore the relationship between LATE, ATE, and effects on the treated in a parametric model that mimics the *same sex* setup.

2.1 A Parametric Example

Following Heckman, Tobias, and Vytlacil (2001), I calculated average causal effects using a trivariate Normal model for the joint distribution of potential outcomes and the error term in the latent-index assignment mechanism given by equation (2). Assuming the distribution of $[Y_{1i} \ Y_{0i} \ \eta_i]'$ is joint standard Normal, ATE is zero by construction. Assume also that $\gamma_1 > 0$ so monotonicity is satisfied with $D_{1i} \geq D_{0i}$ and let ρ_{10} be the correlation between $Y_{1i} - Y_{0i}$ and η_i . In this parametric model, LATE can be written:

$$\begin{aligned} E[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}] &= E[Y_{1i} - Y_{0i} | \gamma_0 + \gamma_1 > \eta_i > \gamma_0] \\ &= \rho_{10} \{ [\Phi(\gamma_0) - \Phi(\gamma_0 + \gamma_1)] [\Phi(\gamma_0 + \gamma_1) - \Phi(\gamma_0)]^{-1} \} \end{aligned} \quad (4)$$

Similarly, we can use Normality to write the effect on the treated as:

$$\begin{aligned} E[Y_{1i} - Y_{0i} | D_i = 1] &= E\{E[Y_{1i} - Y_{0i} | \gamma_0 + \gamma_1 Z_i > \eta_i, Z_i] | D_i = 1\} \\ &= -\rho_{10} \{ \lambda(\gamma_0 + \gamma_1) E(Z_i | D_i = 1) + \lambda(\gamma_0) (1 - E(Z_i | D_i = 1)) \}. \end{aligned} \quad (5)$$

where $\lambda(\cdot)$ is the inverse Mill's ratio, $\phi(\cdot)/\Phi(\cdot)$. This formula is useful for calculation, but the following expression better clarifies the difference between LATE and the effect on the treated:

$$E[Y_{1i} - Y_{0i} | D_i=1] = E[Y_{1i} - Y_{0i} | \gamma_0 + \gamma_1 > \eta_i > \gamma_0] \omega + E[Y_{1i} - Y_{0i} | \gamma_0 > \eta_i] (1 - \omega), \quad (6)$$

where $\omega = \{\Phi(\gamma_0 + \gamma_1) - \Phi(\gamma_0)\} [P(Z_i=1)/P(D_i=1)]$ and $1 - \omega = \Phi(\gamma_0)/P(D_i=1)$. Equation (6) shows the effect on the treated to be a weighted average of LATE and the average effect on those with $\gamma_0 > \eta_i$, with weights that depend on the first stage and the distribution of Z_i .

LATE vs. The Effect on the Treated

LATE and the effect on the treated both depend on the correlation between potential outcomes and the latent first-stage error, and on the first-stage coefficients. The effect on the treated also depends on the distribution of the instrument. The relationship between alternative causal parameters in the parametric model is sketched in Figure 1, which plots ATE (a constant equal to zero), LATE, and the effect on the treated against $\Phi(\gamma_0)$ for a fixed first stage of .07 and an instrument that is Bernoulli(.5). This scenario parallels the *same sex* first stage in Angrist and Evans (1998). The top panel sets $\rho_{10} = -.1$, so that the probability of treatment increases with the gains from treatment, as in a Roy (1951) model, while the bottom panel sets $\rho_{10} = -.5$ for stronger selection on gains. With positive ρ_{10} , the figure would be reflected through the horizontal axis.

The leftmost point in the figure shows that LATE equals the effect on the treated when $\Phi(\gamma_0) = E[D_i | Z_i=0] = 0$. This is incompatible with the Normal latent-index model since it requires $\gamma_0 = -\infty$, but $E[D_i | Z_i=0] = 0$ is an important special case in practice (see, e.g., Bloom, 1984 or Angrist and Imbens, 1991). At the other end of the figure, the effect on the treated approaches the overall average effect when almost everyone gets treated. Finally, Figure 2 shows that increasing the size of the first stage effect from .07 to .30 pulls both LATE and the effect on the treated closer to the overall average effect.

The effect of treatment on the treated is above LATE for all first-stage baseline values, a

consequence of the fact that selection on gains makes $E[Y_{1i} - Y_{0i} | \gamma_0 > \eta_i]$ bigger than LATE. Moreover, LATE provides a better measure of the effect of treatment on a randomly chosen individual (ATE) than does the effect on the treated for most parameter values. A final important feature of the figure (also apparent from equation (4)) is that $LATE=ATE$ when $\gamma_1 = -2\gamma_0$ since $\phi(\gamma_0) = \phi(-\gamma_0)$ by symmetry of the Normal density. Thus, as noted by Heckman and Vytlačil (2000), a “symmetric first stage” that changes the probability of treatment from p to $1-p$ implies LATE equals ATE in the Normal model, or in any latent variable model with jointly symmetric errors.⁵

3. Identification Problems and Prospects

Angrist, Imbens, and Rubin (1996) show that the potential-outcomes framework for IV divides a population into three groups, which I refer to below as “potential-assignment subpopulations.” The first are compliers, i.e., those for whom $D_{1i}=1$ and $D_{0i}=0$. In the latent index model, compliers have $\gamma_0 + \gamma_1 > \eta_i > \gamma_0$. The other two groups include individuals whose treatment status is unaffected by the instrument. One consists of *never-takers*, with $D_{1i}=D_{0i}=0$. Never-takers are never treated regardless of the value of Z_i to which they might be exposed. In the latent index model, never-takers have $\eta_i > \gamma_0 + \gamma_1$. The second unaffected group consists of *always-takers*, with $D_{1i}=D_{0i}=1$. Always-takers are always treated regardless of the value of Z_i to which they might be exposed. In the latent-index model, always-takers have $\gamma_0 > \eta_i$. A possible fourth group with $D_{0i}=1$ and $D_{1i}=0$ is empty by virtue of the monotonicity assumption.

The set of the treated is the union of the disjoint sets of always-takers and compliers with $Z_i=1$. This provides an interpretation for the following identity:

$$D_i = D_{0i} + (D_{1i} - D_{0i})Z_i,$$

⁵Joint symmetry means that if $f(y_{ji}, \eta_i)$ is the joint density of $y_{ji}=Y_{ji}-E[Y_{ji}]$ and η_i , then $f(-y_{ji}, -\eta_i) = f(y_{ji}, \eta_i)$. A weaker condition with the same result (a symmetric first stage ranging from p to $1-p$ gives $LATE=ATE$) is that $E[y_{ji} | \eta_i]$ is an odd function (as for a linear model) and that η_i has a symmetric distribution. Angrist (1991) noted that IV estimates should be close to ATE when the first stage changes the probability of treatment at values centered on one-half, as is required for the first stage to be symmetric.

since $D_{0i}=1$ indicates always-takers and $(D_{1i}-D_{0i})Z_i$, indicates compliers with $Z_i=1$. Since Z_i is independent of complier status, compliers with $Z_i=1$ are representative of all compliers. Causal effects on the treated can therefore be decomposed as:

$$E[Y_{1i} - Y_{0i} | D_i=1] = E[Y_{1i} - Y_{0i} | D_{0i}>D_{1i}](1-P[D_{0i}=D_{1i}=1 | D_i=1]) + \tag{7}$$

$$E[Y_{1i} - Y_{0i} | D_{0i}=D_{1i}=1]P[D_{0i}=D_{1i}=1 | D_i=1].$$

Equation (7) generalizes (6), which gives the same decomposition for the Normal model. Because an instrumental variable provides no information about average treatment effects in the set of always-takers, LATE is identified while $E[Y_{1i}-Y_{0i} | D_i=1]$ is not.

To further pinpoint the identification challenge in this context, note that $E[Y_{1i} | D_{0i}=D_{1i}=1]$ and $E[Y_{0i} | D_{0i}=D_{1i}=0]$ are identified by the following relations:

$$E[Y_{1i} | D_{0i}=D_{1i}=1] = E[Y_{1i} | D_{0i}=1] = E[Y_i | D_i=1, Z_i=0] \tag{8a}$$

$$E[Y_{0i} | D_{0i}=D_{1i}=0] = E[Y_{0i} | D_{1i}=0] = E[Y_i | D_i=0, Z_i=1]. \tag{8b}$$

The missing pieces of the identification puzzle are the fully counter-factual averages, $E[Y_{1i} | D_{0i}=D_{1i}=0]$ and $E[Y_{0i} | D_{0i}=D_{1i}=1]$.

3.1 Restricting Potential-Assignment Subpopulations

The conditional expectation functions (CEFs) of Y_{1i} and Y_{0i} given potential assignments provide a framework for the discussion of alternative identification strategies. These CEFs can be written:

$$E[Y_{1i} | D_{0i}, D_{1i}] = \alpha_1 + \beta_{10}D_{0i} + \beta_{11}D_{1i} \tag{9a}$$

$$E[Y_{0i} | D_{0i}, D_{1i}] = \alpha_0 + \beta_{00}D_{0i} + \beta_{01}D_{1i}. \tag{9b}$$

Equations (9a) and (9b) impose no restrictions since there are three potential-assignment subpopulations and three parameters in each CEF. The 6 conditional means, $E[Y_{ji} | D_{0i}, D_{1i}]$, are uniquely determined by (9a,b) as follows:

<u>Group</u>	<u>Definition</u>	<u>Indicator</u>	<u>CEF for Y_{0i}</u>	<u>CEF for Y_{1i}</u>
Compliers	$D_{1i}=1, D_{0i}=0$	$D_{1i}-D_{0i}$	$\alpha_0 + \beta_{01}$	$\alpha_1 + \beta_{11}$
Always-takers	$D_{1i}=D_{0i}=1$	D_{0i}	$\alpha_0 + \beta_{00} + \beta_{01}$	$\alpha_1 + \beta_{10} + \beta_{11}$
Never-takers	$D_{1i}=D_{0i}=0$	$1-D_{1i}$	α_0	α_1

The CEF for observed outcomes, $E[Y_i | D_i, Z_i]$, has a distribution with 4 points of support, while the CEFs of Y_{0i} and Y_{1i} given D_{0i} and D_{1i} depend on 6 parameters. This suggests the latter are not identified from the former without additional restrictions, a result implied by the theorem below.

THEOREM: *Suppose the Independence, First-Stage, and Monotonicity assumptions hold and that Y_{0i} and Y_{1i} have multinomial distributions. Let $f_0(y | D_{1i}, D_{0i})$ and $f_1(y | D_{1i}, D_{0i})$ denote the conditional distribution functions for potential outcomes given potential assignments and let $f_{YDZ}(y, d, z)$ denote the joint distribution of $Y_i, D_i,$ and Z_i . Then $f_0(y | D_{1i}, D_{0i})$ and $f_1(y | D_{1i}, D_{0i})$ are not identified from $f_{YDZ}(y, d, z)$.*

PROOF: Factor the d.f. using $f_{YDZ}(y, d, z) = f_{YDZ}(y | d, z)g_{DZ}(d, z)$. The second term is unrestricted. Let $f_j(y | D_{1i}, D_{0i}) = \alpha_j(y) + \beta_{j0}(y)D_{0i} + \beta_{j1}(y)D_{1i}$, substitute into $f_{YDZ}(y, d, z)$, and iterate expectations to obtain the multinomial likelihood solely as a function of the parameters determining $f_0(y | D_{1i}, D_{0i})$ and $f_1(y | D_{1i}, D_{0i})$. Finally, substitute for $f_0(y | D_{1i}, D_{0i})$ and $f_1(y | D_{1i}, D_{0i})$ to show the likelihood is invariant to the choice of $\beta_{00}(y)$ and $\beta_{11}(y)$ as long as $\alpha_1(y) + \beta_{11}(y)$ is constant. Non-identification of $\beta_{00}(y)$ implies non-identification of the marginal distribution of Y_{0i} while non-identification of $\beta_{11}(y)$ implies non-identification of the marginal distribution of Y_{1i} .

The multinomial distributional assumption raises the question of how general the theorem is. It seems general enough for practical purposes since, as noted by Chamberlain (1987), any distribution can be approximated arbitrarily well by a multinomial. Moreover, I'd like to rule out identification based on continuity or support conditions to avoid paradoxes such as "identification at infinity".⁶

3.2 A Menu of Restrictions

A variety of restrictions on (9a,b) are sufficient to identify ATE. I briefly discusses 4 cases that strike me as being of special interest. The simplest is ignorable treatment assignment or "no selection bias."

⁶See Chamberlain (1986). The multinomial assumption has some content since it implies that potential outcomes have bounded support, so that ATE and effects on the treated are bounded. See Manski (1990) or Heckman and Vytlacil (2000).

Restriction 1 (no selection bias). $\beta_{00}=\beta_{01}=\beta_{10}=\beta_{11}=0$;

This implies $LATE = \alpha_1 - \alpha_0 = ATE$. Under Restriction 1, ATE can be estimated from simple treatment-control comparisons.

Because the assumption of no selection bias involves four restrictions while two would be sufficient, ATE is over-identified in this case.⁷ A standard Hausman (1978) test for endogeneity exploits over-identification by comparing IV and OLS estimates, equivalent here to a comparison of Wald estimates with treatment-control differences. A modified and potentially more powerful test can be based on the fact that under Restriction 1, $E[Y_{1i} | D_{0i}=1]=\alpha_1$ and $E[Y_{0i} | D_{1i}=0]=\alpha_0$. Using (8a,b), this suggests the following specification test:

Test for Selection Bias.

$$\frac{E[Y_i | Z_i=1] - E[Y_i | Z_i=0]}{E[D_i | Z_i=1] - E[D_i | Z_i=0]} = \{E[Y_i | D_i=1, Z_i=0] - E[Y_i | D_i=0, Z_i=1]\}. \quad (T1)$$

In the appendix, I show how a test statistic based on T1 can be computed using regression software.

The Hausman test for selection bias replaces $E[Y_i | D_i=1, Z_i=0] - E[Y_i | D_i=0, Z_i=1]$ on the right hand side of T1 with $E[Y_i | D_i=1] - E[Y_i | D_i=0]$. The Hausman test will also work in the causal framework outlined here since under Restriction 1 both OLS and IV estimate ATE. The difference between T1 and a Hausman test arises from the fact that the Hausman test implicitly compares $E[Y_{ji} | D_{1i} > D_{0i}]$ with $E[Y_{ji} | D_i=j]$ for $j=0,1$, while T1 implicitly compares $E[Y_{ji} | D_{1i} > D_{0i}]$ with $E[Y_{ji} | D_{1i} = D_{0i} = j]$ for $j=0,1$. These two pairs of comparisons are the same under monotonicity but not in general. The empirical results below suggest that T1, which uses

⁷A weaker version of Restriction 1 with $\beta_{11}=\beta_{00}=0$ is also sufficient to identify ATE since this equates never-takers with compliers for the CEF of Y_{1i} and always-takers with compliers for the CEF of Y_{0i} . This seems no easier to motivate than Restriction 1, so I limit the discussion to the over-identified case.

monotonicity, indeed provides a more powerful specification test.⁸

While pivotal for specification testing, the assumption of no selection bias is an unattractive basis for causal inference since the use of IV is motivated by the possibility of selection bias. An alternative assumption that allows for selection bias amounts to the claim that the difference between $Y_{1i} - Y_{0i}$ is mean-independent of potential treatment assignments. I refer to this as “conditional constant effects.” Formally, this means:

Restriction 2 (conditional constant effects). $\beta_{00} = \beta_{10}; \beta_{01} = \beta_{11}$.

This pair of restrictions is just sufficient to identify ATE. In particular, we again have $LATE = \alpha_1 - \alpha_0 = ATE$. Restriction 2 rules out Roy (1951) type selection, where treatment status is determined in part by the gains from treatment. On the other hand, Restriction 2 is weaker than the usual constant-effects assumption in that it does not require a deterministic link between Y_{1i} and Y_{0i} .⁹

A third restriction, which I call “linearity,” is appealing because it is not fundamentally inconsistent with a benchmark Roy-type selection model. The linearity condition is:

Restriction 3 (linearity). $\beta_{00} = \beta_{01}; \beta_{10} = \beta_{11}$.

In this case, the potential-outcomes CEFs can be written:

$$E[Y_{1i} | D_{0i}, D_{1i}] = \alpha_1 + \beta_{11}(D_{0i} + D_{1i}) \tag{10a}$$

$$E[Y_{0i} | D_{0i}, D_{1i}] = \alpha_0 + \beta_{01}(D_{0i} + D_{1i}). \tag{10b}$$

⁸Abadie (2002) develops a number of related bootstrap specification tests.

⁹Note that the first part of Restriction 2 is sufficient to identify the effect of treatment on the treated, while the second part is sufficient to identify the effect of treatment on the non-treated. Although conditional constant effects is the basis of much empirical work and may be a reasonable approximation for practical purposes, as a theoretical matter this is typically implausible unless treatment is exogenous; see, e.g., Wooldridge (1997, 2003).

Restriction 3 requires the potential-outcomes CEF to be linear in $D_i^* \equiv D_{0i} + D_{1i}$, where D_i^* is a summary measure of the desire or suitability of an individual for treatment. If the restriction is false, we can nevertheless think of (10a) and (10b) as providing a minimum mean-squared error approximation to the unrestricted model, (9a) and (9b).

To see how average causal effects are identified under Restriction 3, write the probabilities of being an always-taker and never-taker as

$$P[D_{0i}=D_{1i}=1] = E[D_{0i}] = p_a$$

$$P[D_{0i}=D_{1i}=0] = E[1-D_{1i}] = p_n.$$

and note that

$$E[D_{0i} + D_{1i}] = 1 + (p_a - p_n).$$

Substitute into (10a) and (10b) and difference to obtain

$$\begin{aligned} E[Y_{1i} - Y_{0i}] &= [(\alpha_1 + \beta_{11}) - (\alpha_0 + \beta_{01})] + (\beta_{11} - \beta_{01})(p_a - p_n) \\ &= E[Y_{1i} - Y_{0i} \mid D_{1i} > D_{0i}] \\ &\quad + \{(E[Y_{1i} \mid D_{0i}=1] - E[Y_{1i} \mid D_{1i} > D_{0i}]) - (E[Y_{0i} \mid D_{1i} > D_{0i}] - E[Y_{0i} \mid D_{1i}=0])\}(p_a - p_n). \end{aligned} \quad (11)$$

The components on the right hand side of (11) are easily estimated; details are given in the appendix.

A calculation similar to that used to derive (11) shows that the effect of treatment on the treated can be constructed using

$$\begin{aligned} E[Y_{1i} - Y_{0i} \mid D_i=1] &= [(\alpha_1 + \beta_{11}) - (\alpha_0 + \beta_{01})] + (\beta_{11} - \beta_{01})(p_a/p_d) \\ &= E[Y_{1i} - Y_{0i} \mid D_{1i} > D_{0i}] \\ &\quad + \{(E[Y_{1i} \mid D_{0i}=1] - E[Y_{1i} \mid D_{1i} > D_{0i}]) - (E[Y_{0i} \mid D_{1i} > D_{0i}] - E[Y_{0i} \mid D_{1i}=0])\}(p_a/p_d), \end{aligned} \quad (12)$$

where p_d is the probability of treatment. From (12), we can immediately derive the Bloom (1984) result that if there are no always-takers, LATE is the effect on the treated.¹⁰

¹⁰With no always-takers, we have $D_{0i} \equiv 0$, so Restriction 3 is not binding.

3.1 Symmetry Revisited

Restriction 3 is closely related to the symmetry property discussed in the parametric example. To see this, note that as a consequence of linearity we can interpolate the CEF for compliers by averaging as follows:

$$E[Y_{ji} | D_{1i} > D_{0i}] = \{E[Y_{ji} | D_{0i}=1] + E[Y_{ji} | D_{1i}=0]\}/2. \quad (13)$$

What distributional assumptions support a relation like (13)? Suppose treatment is determined by a latent-index assignment mechanism, as in equation (2). Then,

$$E[Y_{ji} | D_{1i} = D_{0i} = 0] = E[Y_{ji} | \eta_i > \gamma_0 + \gamma_1]$$

$$E[Y_{ji} | D_{1i} = D_{0i} = 1] = E[Y_{ji} | \eta_i < \gamma_0],$$

and

$$E[Y_{ji} | D_{1i} > D_{0i}] = E[Y_{ji} | \gamma_0 + \gamma_1 > \eta_i > \gamma_0].$$

If in addition, $\gamma_1 = -2\gamma_0$, then equation (13) holds as long as (Y_{ji}, η_i) is jointly symmetric, as in the Normal model. The restriction $\gamma_1 = -2\gamma_0$ implies

$$P[D_i=1 | Z_i=0] = P[\eta_i < \gamma_0] = 1-p \quad (14)$$

$$P[D_i=1 | Z_i=1] = P[\eta_i < -\gamma_0] = p$$

for some $p \in [0,1]$ so the first stage is also symmetric (e.g, a first stage effect of .1 that shifts the probability of treatment from $1-p=.45$ to $p=.55$).

The upshot of the previous discussion is that a symmetric latent error distribution and a symmetric first stage imply the interpolating property, (13), or, equivalently, Restriction 3. Moreover, we again have LATE equals ATE since $p_a = p_n$ given the first stage described in (14).¹¹ Intuitively, a symmetric first-stage with symmetrically distributed latent errors equates LATE with ATE because average treatment effects for

¹¹To see this, note that $P[D_i=1 | Z_i=0]=1-p$ implies $p_a = 1-p$. Since $p_a + p_n + \{P[D_i=1 | Z_i=1]-P[D_i=1 | Z_i=0]\} = (1-p) + p_n + (2p-1)=1$, this implies $p_n=1-p$. As noted in the discussion of the parametric model, LATE=ATE given (14) also results when $E[y_{ji} | \eta_i]$ is an odd function and the marginal distribution of η_i is symmetric. This makes it possible to have a relation like (13) with, say, a binary or otherwise limited dependent variable for which a symmetric distribution is implausible.

individuals with characteristics that place them in the middle of the η_i distribution (compliers) are representative of average treatment effects for individuals over the entire distribution of η_i .

A first-stage relationship may be fortuitously symmetric, as for the 1990 Census sample of teen mothers using the *same sex* instrument. In such cases, it seems reasonable to invoke Restriction 3 and proceed under the assumption that LATE equals ATE. But what if, as seems more typical, the first stage shifts the probability of treatment asymmetrically? In the empirical section, I describe a simple scheme for using covariates to construct a subsample with a symmetric first stage. IV should estimate average treatment effects in this specially constructed sample. This approach naturally raises the question of how to use average treatment effects for one sample to make inferences about average effects in another. For a recent attack on this question, see Hotz, Imbens and Klerman (2000), who outline a procedure designed to extrapolate the results from randomized trials across sites with different populations. Here I rely on the fact that if effects differ little between two samples with and without a symmetric first-stage, then given Restriction 3, the extrapolation problem is solved under the maintained assumption that average treatment effects would be similar in the symmetric sample and its complement.

3.2 Weakening Restriction 3

Suppose again that treatment assignment can be modeled using equation (2), and that the potential-outcomes CEFs are linear in η_i (as would be the case under joint Normality). Then we can write,

$$E[Y_{1i} | D_{0i}, D_{1i}] = \alpha_1 + \rho_1 E[\eta_i | D_{0i}, D_{1i}] \quad (15a)$$

$$E[Y_{0i} | D_{0i}, D_{1i}] = \alpha_0 + \rho_0 E[\eta_i | D_{0i}, D_{1i}] \quad (15b)$$

where

$$E[\eta_i | D_{0i}, D_{1i}] = E[\eta_i | D_{1i}=0] + \{E[\eta_i | D_{0i}=1] - E[\eta_i | D_{1i}=1, D_{0i}=0]\} D_{0i} + \{E[\eta_i | D_{1i}=1, D_{0i}=0] - E[\eta_i | D_{1i}=0]\} D_{1i}. \quad (16)$$

Substituting (16) into (15a) and (15b) generates an expression for the coefficients in (9a), (9b). This leads

to the following generalization of Restriction 3:

Restriction 4 (proportionality). $\beta_{00}=\theta\beta_{01}$; $\beta_{10}=\theta\beta_{11}$, for $\theta>0$.

The first part of the proportionality restriction comes from (15a,b) alone. Using (16), we have

$$\theta = \{E[\eta_i | D_{0i}=1] - E[\eta_i | D_{1i}=1, D_{1i}=0]\} / \{E[\eta_i | D_{1i}=1, D_{0i}=0] - E[\eta_i | D_{1i}=0]\}, \quad (17)$$

which shows why θ is positive.

Restriction 4 leads to a generalization of the interpolation formula for average potential outcomes.

In particular, we now have

$$E[Y_{ji} | D_{1i} > D_{0i}] = (1/(1+\theta))E[Y_{ji} | D_{0i}=1] + (\theta/(1+\theta))E[Y_{ji} | D_{1i}=0], \quad (18)$$

so that if $\theta=0$, compliers have the same expected potential outcomes as always-takers, while as θ approaches infinity, compliers have the same expected potential outcomes as never-takers.

The linearity assumption used to motivate Restriction 4 seems most plausible in the context of a model for continuous outcomes. It may be more of stretch, however, for binary outcomes such as marital status. On the other hand, without covariates the distribution of η_i is arbitrary. We can therefore define η_i as the latent error term in an assignment mechanism like (2), after transformation to a uniform distribution on the unit interval.¹² This guarantees that (15a,b) can generate fitted values for outcome CEFs that also fall in the unit interval. Alternately, the weighted average in (18) can be motivated directly as a natural generalization of equally-weighted interpolation using (13).

To develop an estimator using (18), substitute Restriction 4 into (9a) and (9b) to obtain:

$$E[Y_{1i} | D_{0i}, D_{1i}] = \alpha_1 + \beta_{11}(\theta D_{0i} + D_{1i})$$

$$E[Y_{0i} | D_{0i}, D_{1i}] = \alpha_0 + \beta_{01}(\theta D_{0i} + D_{1i}).$$

Differencing and averaging, we have

¹²The requires that the underlying error have a continuous distribution.

$$\begin{aligned}
E[Y_{1i} - Y_{0i}] &= [(\alpha_1 + \beta_{11}) - (\alpha_0 + \beta_{01})] + (\beta_{11} - \beta_{01})(\theta p_a - p_n) \\
&= E[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}] \\
&\quad + \{\theta^{-1}(E[Y_{1i} | D_{0i}=1] - E[Y_{1i} | D_{1i} > D_{0i}]) - (E[Y_{0i} | D_{1i} > D_{0i}] - E[Y_{0i} | D_{1i}=0])\}(\theta p_a - p_n).
\end{aligned} \tag{19}$$

We can map out the values of ATE consistent with the data by evaluating (19) for alternative choices of θ . This sensitivity analysis is subject to the caveat that at the extremes where θ equals zero or infinity, ATE is not identified, a fact apparent from (18).¹³

An alternative to sensitivity analysis is to try to estimate θ using (17). Although θ is not identified without further assumptions, it clearly depends in large part on the first stage coefficients, γ_0 and γ_1 . This suggests a strategy for estimating θ using information on these coefficients only. Suppose that (15a,b) holds for a latent error transformed to Uniform as discussed above, or that the CDF of η_i can be approximated by a uniform distribution on the unit interval. Then a straightforward calculation gives

$$\theta = [\gamma_0 + \gamma_1] / [1 - \gamma_0] = P(D_i=1 | Z_i=1) / [1 - P(D_i=1 | Z_i=0)]. \tag{20}$$

This has the property that $\theta=1$ when $P(D_i=1 | Z_i=1)=1-P(D_i=1 | Z_i=0)$, while capturing deviations from symmetry in a straightforward manner. The value of θ calculated using (20) in the 1990 Census sample analyzed here is .61, close to the value calculated using Normality (.58).

Specification Tests for Homogeneity Restrictions

Because ATE is – by definition – invariant to the particular instrument used to estimate it, Restrictions 2, 3, and 4 can be partly checked by comparing alternative estimates using different instruments. In the case of Restriction 2, this amounts to a Sargan (1958) over-identification test comparing alternative IV estimates of the same structural coefficient. Under Restrictions 3 and 4, the relevant comparison should use equation (19) to convert estimates of LATE into estimates of ATE. A final set of specification tests is suggested by the fact that under Restrictions 3 or 4,

¹³To compute the effect of treatment on the treated under Restriction 4, replace $\theta p_a - p_n$ with $\theta p_a / p_d$ in (19).

$$E[Y_{1i} - Y_{0i} | D_{1i}, D_{0i}] = (\alpha_1 - \alpha_0) + (\beta_{11} - \beta_{01})(\theta D_{0i} + D_{1i}).$$

A test of whether $\beta_{11} - \beta_{01}$ equals zero is therefore a test of conditional constant effects, while a test of whether $\beta_{11} - \beta_{01}$ is positive is a test for Roy-type selection on the gains from treatment.

4. Childbearing, Marital Status, and Economic Welfare

The *same sex* instrument is a dummy for having two boys or two girls at first and second birth. Angrist and Evans (1998) showed this instrument increases the likelihood mothers with at least two children go on to have a third child by about 6-7 percentage points, but is otherwise uncorrelated with mothers' demographic characteristics. The data set used here is the 1990 Census extract used in the Angrist and Evans paper. This sample includes mothers aged 21-35 with two or more children, the oldest of whom was less than 18 at the time of the Census.

Descriptive statistics are reported in Table 1 for the full sample, for a subsample of ever-married women, and for four subsamples defined by mothers' education and age at first birth. The division into subsamples was motivated by earlier results showing markedly different effects of childbearing by maternal education, and because of the policy interest in teen mothers. The probability of having a third child ranges from a low of .33 in the sample of women with some college, to a high of .5 in the sample of teen mothers. The probability of having a same-sex sibling pair is more or less constant at .505. Some of the estimates control for the demographic covariates listed in Table 1 using linear models.¹⁴ Means for the outcome variables of interest appear at the bottom of Table 1.

4.1 OLS, IV, and 2SLS Estimates

The effect of *same sex* on the probability of having a third child varies from a low of 5.9 percentage points in the some-college sample to a high of 6.5 percentage points in the no-college sample. This can be

¹⁴See Abadie (2003) and Frolich (2002) for nonlinear causal models with covariates.

seen in the first row of Table 2, which reports first-stage estimates.¹⁵ As a benchmark, the next two rows of Table 2 show estimates of the effect of childbearing on two of the labor supply variables studied by Angrist and Evans (1998). These are IV and OLS estimates from models without covariates, i.e., Wald estimates and simple treatment-control contrasts.

The Wald (IV) estimates of the effect of a third child on employment status and weeks worked suggest mothers reduced their labor supply as a consequence of childbearing, though not by as much as indicated by the OLS estimates. For example, women who had a third child were about 13 percentage points less likely to work, but the corresponding IV estimate suggests a causal effect of only 8 percentage points. The OLS and IV estimates for weeks worked are about -7 and -5. The IV estimates of labor supply effects are larger for less-educated women than for those with some college; in fact, the labor supply estimates are not significant in the some-college sample. In contrast, the IV estimates are smaller for women who had their first birth as teenager than for women who had their first birth as an adult.

The last two rows in Table 2 show first-stage, OLS and two-stage least squares (2SLS) estimates after adding controls for age, age at first birth, dummies to indicate first-born and second-born boys, race dummies, and dummies for three schooling groups. Since *same sex* is uncorrelated with these covariates, including them has little effect on the 2SLS estimates. Moreover, in spite of the fact that some of the covariates are good predictors of outcomes, estimates with covariates are only slightly more precise than those without. Perhaps more surprisingly, the OLS estimates of labor supply effects also change little in response to the addition of covariates.

Estimates of the effect of having a third child on marital status, poverty status, and welfare use are reported in Table 3 for models with and without covariates. In the sample of all women, those with more children are less likely to be married. But this is at least in part due to uncontrolled demographic factors such

¹⁵The difference in first-stage estimates across samples characterizes the distribution of covariates among compliers since, for a binary covariate, x_i , $E[x_i | D_{1i} > D_{0i}] / E[x_i] = E[D_{1i} - D_{0i} | x_i = 1] / E[D_{1i} - D_{0i}]$. Table 2 therefore shows *same sex* compliers to be less educated and more likely to have been married than the overall average.

age at first birth, since OLS estimates with controls show that additional childbearing is associated with an increase in the likelihood of being married. In contrast to the OLS estimates, IV estimates with or without covariates suggest that the causal effect of childbearing is a reduced probability of being married. Thus, an important finding is that when the effect of childbearing is estimated in models with demographic controls, IV and OLS estimates have opposite signs.

The most important change in marital status caused by childbearing appears to be an increase in the likelihood of being divorced or separated. The estimated effects of childbearing on the probability of being ever-married or divorced (but not separated) are not significantly different from zero. Consistent with an increase in marital breakup, the birth of a third child also appears to lead to a marked increase in the likelihood a woman lives in a family with total family income below the poverty line. Here we should expect at least a mechanical effect since the poverty threshold falls as family size increases. Although OLS estimates are larger than IV estimates in models without covariates, OLS and IV estimates in models with covariates both indicate that a third child increases the likelihood a woman is poor by 9-10 percentage points.

Given the elevated rates of marital breakup and the increase in poverty rates that appear to be caused by childbearing, it seems reasonable to expect that the birth of a third child also increases the likelihood a woman is on welfare. Both the IV and OLS estimates tend to support this, though the IV estimates are imprecise. The OLS estimate of the effect on welfare use range from 6.7 percentage points without covariates to 3.9 percentage points with covariates. The IV estimate is a marginally significant 3.3 percent with or without covariates. While small in levels, an effect of this magnitude represents a roughly one-third increase in the number of women on welfare.

The IV estimates show no relationship between childbearing and the probability a woman has ever been married, so estimates limited to the sample of ever-married women are unlikely to be affected by selection bias. Not surprisingly, therefore, the IV estimates in the sample of ever-married women are almost identical to those in the full sample. On the other hand, while the IV estimate of the reduction in marriage

rates is a significant 8 percentage points (s.e.=.028) for women with no college, it is close to zero and insignificant for women with some college. The effects of childbearing on poverty are also larger in the no-college sample, though the difference in effects on welfare use by college status is reversed and much smaller than the difference in effects on poverty rates.

The difference in estimates by mothers' age at first birth also suggest a pattern of larger effects with decreasing socioeconomic status, though the contrast is not as clear cut as the differences by schooling group. While the increases in marital dissolution and welfare receipt are larger for teen mothers than for adult mothers, the estimates are significant only in the latter group. Estimates of effects on divorce/separation are similar in the two groups, though again much more precise for the sample of adult mothers. This difference in precision undoubtedly reflects the smaller sample of teen mothers. One clear contrast, however, is the higher likelihood that a third birth pushes a teen mother into poverty. The impact on poverty status is significant regardless of mothers' age at first birth, but it is roughly three times larger for teen mothers.

4.2 Heterogeneity across potential-assignment subpopulations

The first-stage estimates imply that 6-7 percent of each sample consists of compliers, i.e., mothers who had a child in response to a homogenous sibling-sex mix. Because the overall probability of treatment ranges upwards from about .32, the overwhelming majority of treated individuals are always-takers. This can be seen in Table 4, which gives the distribution of potential-assignment subpopulations. In the sample of all women, for example, 6.3 percent are compliers, 34 percent are always-takers (i.e., have a third child without regard to sibling-sex composition), and 59 percent are never-takers (i.e., would never have a third child regardless of sibling-sex composition). The proportion of treated who are compliers is $1 - (p_a/p_d)$, or about 8 percent. Given the relatively small proportion of compliers, the scope for differences in average causal effects across potential-assignment subpopulation is substantial.

Table 4 also reports the estimate of $(p_a - p_n)$, the multiplier that determines how far LATE is from ATE when the latter is calculated using Restriction 3 and equation (11), or in models with covariates as

described in the Appendix. The estimate of $(p_a - p_n)$ is $-.25$ in the full sample, and ranges from 0 for teen mothers to $-.352$ in the sample of adult mothers.

Symmetric subpopulations

The value of zero for $(p_a - p_n)$ in the teen mother sample is noteworthy because it means that LATE is the same as ATE under Restriction 3. This is a consequence of the fact that the first stage for teen mothers is almost perfectly symmetric: the *same sex* instrument shifts the probability of further childbearing from about $.47$ to $.53$. Moreover, because θ for teen mothers is about 1 when estimated using (20), estimates of ATE for teen mothers under Restriction 4 are also close to LATE.

The first two columns of Table 5 focus on the comparison between estimates for all women and teen mothers only, repeating earlier estimates for these samples from Table 3 without covariates, including the first-stage coefficient and intercept. For the most part, IV estimates for teen mothers are similar to those for the sample of all women. While the estimated effect on employment is considerably lower at $-.026$ (s.e.=.051) versus $.084$ (s.e.=.027) in the full sample, the effect of childbearing on weeks worked is -5.2 (s.e.=1.3) in the full sample and -4.8 (s.e.=2.4) for teen mothers. Similarly, the effect on marital status is $-.062$ (s.e.=.024) in the full sample and $-.066$ for teen mothers (.051). Note that we can view the parameters estimated in the full sample as estimates of $E[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}, X = \text{all women}]$, while the estimates in column 2, for teen mothers, can be interpreted as measuring $E[Y_{1i} - Y_{0i} | X = \text{teen mothers}]$ under Restriction 3 or 4. A test of equality across columns 1 and 2 is therefore a joint test of the invariance of average treatment effects to conditioning both on X and on the compliers potential-outcomes subpopulation. The fact that these are similar is evidence against substantial treatment effect heterogeneity in both dimensions, though of course there are scenarios where this test has no power.¹⁶

There is some evidence for a difference in effects on poverty status between the teen mother and all-

¹⁶As with an over-identification test, the power of the test turns on maintaining the validity of a benchmark. Here, we maintain $E[Y_{1i} - Y_{0i} | X = \text{teen mothers}] = E[Y_{1i} - Y_{0i}]$.

women samples. For all women, the IV estimate of the effect of childbearing on poverty status is .095 (s.e.=.023), while the corresponding estimate is .143 (s.e.=.05) in the teen mother sample. The comparison across samples is weakened, however, by the fact the estimates in the teen mother sample are much less precise than in the full sample. This raises the question of whether we can construct a larger sample with a symmetric first stage. I attempted to construct such a sample by estimating a Probit first-stage allowing interactions with covariates and then selecting the sample based on covariate-specific fitted values.¹⁷

The details of the symmetric sample selection are as follows. First I estimated the Probit first-stage:

$$P[D_i=1 | Z_i, X_i] = \Phi[\kappa_0'X_i + (\kappa_1'X_i)Z_i], \quad (21)$$

where X_i is a vector of covariates that includes age, age at first birth, Black and Hispanic dummies, and dummies indicating women with some college and college graduates. The main effects, $\kappa_0'X_i$, and interaction terms, $\kappa_1'X_i$, use the same parameterization of covariate effects. In practice, $\kappa_0'X_i$ has about 1,700 points of support. For each of these points, I calculated

$$\hat{\pi}_0(X_i) \equiv \Phi[\hat{\kappa}_0'X_i],$$

the distribution of which is plotted in Figure 3. The distribution of $\hat{\pi}_0(X_i)$ is concentrated around the overall average of about .34.

A symmetric first stage necessarily shifts the probability of treatment across the value of one-half. Column 3 of Table 5 reports estimates for the sample with $\hat{\pi}_0(X_i)$ between .4 and .6. In this sample, with about 104,000 observations, the estimated first-stage shifts the probability of treatment from .47 to .54. For most outcomes, the IV estimates in this symmetric sample are smaller in absolute value than in the full sample, and smaller than in the sample complementary to this, for which results are reported in column 4. For example, the estimated effect on weeks worked in the symmetric sample is -3.7 (s.e.=2.2), while the corresponding estimate in the complementary sample is -6 (s.e.=1.6). Again, however, the comparison is handicapped by a lack of precision.

¹⁷A maintained assumption here is that the distribution of y_{ji} and η_i is jointly symmetric conditional on the covariates used to select the sample with a symmetric first stage.

The long right tail of the distribution of first-stage base values plotted in Figure 3 suggests that an even larger symmetric sample can be constructed simply by dropping values of $\hat{\pi}_0(X_i)$ beginning from the left and working up. As it turns out, limiting the sample to individuals with values of $\hat{\pi}_0(X_i)$ greater than or equal to .35 leads to a first stage that shifts the probability of treatment from .465 to .533, virtually perfectly symmetric. This can be seen in column 5 of Table 5, which reports first-stage and IV estimates for the resulting sample of 162,264 observations. Most of the estimates in this symmetric sample are close to those in the full sample. For example, the effect on weeks worked is -5.9 (s.e.=1.8) and the effect on divorce or separation is .068 (s.e.=.032). Perhaps surprisingly, the estimated effect on poverty status differs markedly between this sample and its complement (.136 versus .048), but the estimated effect is still significantly different from zero in the complementary sample.

Imputation of ATE

The results in Table 5 reflect an attempt to identify or construct samples where LATE=ATE. Alternately, we can use equations (11) or (19) to impute a value of ATE for the various subsamples analyzed in Table 3. The results of this effort are presented in Table 6 for four outcomes; this table also reports the no-selection alternative used to construct the specification test discussed at the beginning of Section 3.2. The estimates of the no-selection alternative are all slightly farther from the estimates of LATE than the corresponding OLS estimates. For example, the OLS estimate of the effect on weeks worked in the full sample is -7.34 (s.e.=.08), while the no-selection alternative is -7.56 (s.e.=.12). This suggests, as noted earlier, that the contrast between IV and the no-selection alternative provides a more powerful specification test than a conventional IV/OLS comparison.

Estimates of ATE constructed using equation (11) for the effect of childbearing on weeks worked are similar to the estimates of LATE, even in samples where the first-stage is not symmetric. For example, the estimate of ATE for the sample of non-teen (i.e., adult) mothers is -4.1 (s.e.=1.5), in comparison with an estimate of LATE of -5.3 (s.e.=1.6). Using the estimates of θ shown in Table 4 and equation (19) generates

somewhat smaller estimates for the effect on weeks worked other than in the teen mother sample, though again mostly still significant.

Estimates of ATE for outcomes other than weeks worked are mostly insignificant. This contrasts with the mostly significant estimates of LATE. Again, this is partly a problem of precision. But the estimates of ATE outside the teen mother sample move substantially closer to zero than the estimates of LATE. For example, while LATE suggests the probability of divorce or separation increases by .053 (s.e.=.019), the corresponding estimates of ATE are .028 (s.e.=.019) when θ equals one and .009 (s.e.=.021) when θ is estimated. The evidence that further childbearing increases divorce or separation for the typical woman with two children is therefore weaker than the estimates of LATE would suggest. Except for the sample of teen mothers, the estimates of ATE for effects on poverty status are also smaller than the corresponding estimates of LATE.

5. Summary and Conclusions

The framework outlined here provides a strategy for modeling treatment effect heterogeneity across potential-assignment subpopulations. I focused initially on restrictions that make IV estimates of causal effects on compliers representative of the overall population average treatment effect. The framework also leads to procedures that can be used to impute average treatment effects from information on average outcomes for compliers, always-takers, and never-takers. An illustration of these ideas using *same sex* instruments suggests this approach may be useful in applied work.

On the empirical side, estimates of LATE for teen mothers are close to the corresponding average treatment effects for this population. And while estimates of the overall average effect of childbearing are smaller than the corresponding IV estimates, most of the estimated effects on labor supply and poverty status remain substantial and significant. On the other hand, most (though not all) of the estimated average effects on marital status and welfare use are small and insignificant.

Estimates using the *same sex* instrument suggest the outline of a coherent picture, but many features

remain unresolved. In practice, the theory of parameter heterogeneity runs quickly into the sandpile of sampling variance and specification uncertainty. On balance, I think extrapolation efforts of the sort implemented here are more likely to weaken the case for the predictive value of a particular causal estimate than to provide a concrete and precise alternative to traditional IV. For example, the evidence for an adverse effect of childbearing on marital stability and welfare use is clearly weakened by the attempt to go from LATE to ATE. This sort of destructive evidence seems to me to be a prominent feature of life in the empirical world. The external validity of IV estimates is ultimately established less by new econometric methods than by replication in new data sets, and, of course, by new instruments.

APPENDIX: COMPUTATION

1. The selection test.

Drop individual subscripts from the notation. Consider the following two-equation system:

$$Y = \Delta_0 + \Delta_1 D + \mu \tag{A1}$$

$$Y = \delta_0 + \delta_1(1[D=Z]) + \delta_2((D-Z)/2) + v \tag{A2}$$

The test for selection bias is a test of whether $\Delta_1 = \delta_2$ when (A1) is estimated by IV using Z as an instrument and A2 is estimated by OLS. The two coefficients and the asymptotic standard error for their difference can be estimated by stacking A1 and A2 and allowing for heteroscedastic and correlated residuals. In practice, for sample sizes on the order of that used here, it seems reasonable to treat the estimate of δ_2 as non-stochastic and use the standard error of the estimate of Δ_1 to construct a t-test.

2. Estimates under Restriction 3.

Use (A2) to write:

$$E[Y_1 | D=1, Z=0] = E[Y_1 | D_1=D_0=1] = \delta_0 + \delta_2/2$$

$$E[Y_0 | D=0, Z=1] = E[Y_1 | D_1=D_0=0] = \delta_0 - \delta_2/2.$$

Estimates of $E[Y_0 | D_1 > D_0]$ and $E[Y_1 | D_1 > D_0]$ can be obtained as IV estimates of the coefficients Δ_{01} and Δ_{11} in (A3) and (A4), below:

$$DY = \Delta_{10} + \Delta_{11}D + \mu_1 \tag{A3}$$

$$(1-D)Y = \Delta_{00} + \Delta_{01}(1-D) + \mu_0. \tag{A4}$$

Estimates of ATE under Restriction 3 are a linear combination of δ_0 , δ_2 , Δ_{01} , and Δ_{11} . These coefficients and the standard error for any linear combination of them can be estimated by stacking A2, A3, and A4.

To further simplify, rewrite equation (11) in terms of the parameters in A2-A4 as

$$E[Y_1 - Y_0] = \Delta_{11}[1 - (p_a - p_n)] - \Delta_{01}[1 + (p_a - p_n)] + 2\delta_0(p_a - p_n). \quad (\text{A5})$$

To accommodate models with covariates, it is convenient to use a regression set-up to estimate $p_a - p_n$. Define a dependent variable $d^* = D(2Z - 1) - Z$. Regress d^* on Z ; the coefficient on Z is an estimate of $p_a - p_n$. Note that (without covariates) the standard error for the estimated $p_a - p_n$ is the same as the standard error for the first-stage coefficient since the latter can be written $1 - p_n - p_a$. To estimate $E[Y_1 - Y_0 | D=1]$, replace $p_a - p_n$ with p_a/p_d in (A5).

Models with covariates were estimated by adding covariates to the relevant first-stage equations, and to equations A1-A4. As a shortcut for inference for estimates of ATE using A5, it seems reasonable to treat $(p_a - p_n)$ and δ_0 as known since these are estimated much more precisely than Δ_{11} and Δ_{01} , which are themselves instrumental variables estimates. Note also that IV estimates of Δ_{11} and Δ_{01} are independent.

3. Estimates under Restriction 4.

Substitute parameters from A1-A4 into (19) and simplify to obtain

$$E[Y_1 - Y_0] = \Delta_{11}[1 - (p_a - \theta^{-1}p_n)] - \Delta_{01}[1 + (\theta p_a - p_n)] + [\delta_0(1 + \theta^{-1}) + (\delta_2/2)(\theta^{-1} - 1)](\theta p_a - p_n). \quad (\text{A6})$$

Standard errors were calculated treating p_a , p_n , δ_0 , δ_2 , and θ as known.

TABLE 1: DESCRIPTIVE STATISTICS, WOMEN AGED 21-35 WITH 2 OR MORE CHILDREN

Notes: Data are from the 1990 PUMS. The sample includes women with 2 or more children whose 2nd child was at least age 1 and who had their first birth at age 15 or later. The no-college sample includes women with no college or with an associate occupational degree. The some-college sample includes women with an associate academic degree, some college but no degree, or a college degree. Teen mothers are those who had their first birth at age 19 or younger. Standard deviations are reported in parentheses. All calculations use sample weights.

Notes: The first column reports the proportion treated. The second column shows the proportion of compliers in the sample, which is given by the first-stage effect of *Same sex*. The estimates of the proportion of always-takers and never-takers and the parameter θ were calculated as described in the text. Estimates with covariates were calculated as described in the appendix. Standard errors are reported in parentheses. All calculations use sample weights.

TABLE 5: SYMMETRIC FIRST STAGE SAMPLES - NO COVARIATES

Variables	All Women (1)	Teen Mothers (2)	Symmetric Sample I		Symmetric Sample II	
			$\pi_0(X) \geq 0.4$ & $\pi_0(X) \leq 0.6$ (3)	$\pi_0(X) < 0.4$ or $\pi_0(X) > 0.6$ (4)	$\pi_0(X) \geq 0.35$ (5)	$\pi_0(X) < 0.35$ (6)

Notes: Columns 1 and 3 repeat estimates from Tables 2 and 3. Column 2 shows the no-selection alternative under Restriction 1 and for the selection-bias test. Column 4 reports estimates of ATE under Restriction 3 and column 5 reports estimates of ATE under Restriction 4.

Panel A: Moderate selection on gains

Panel B: Strong selection on gains

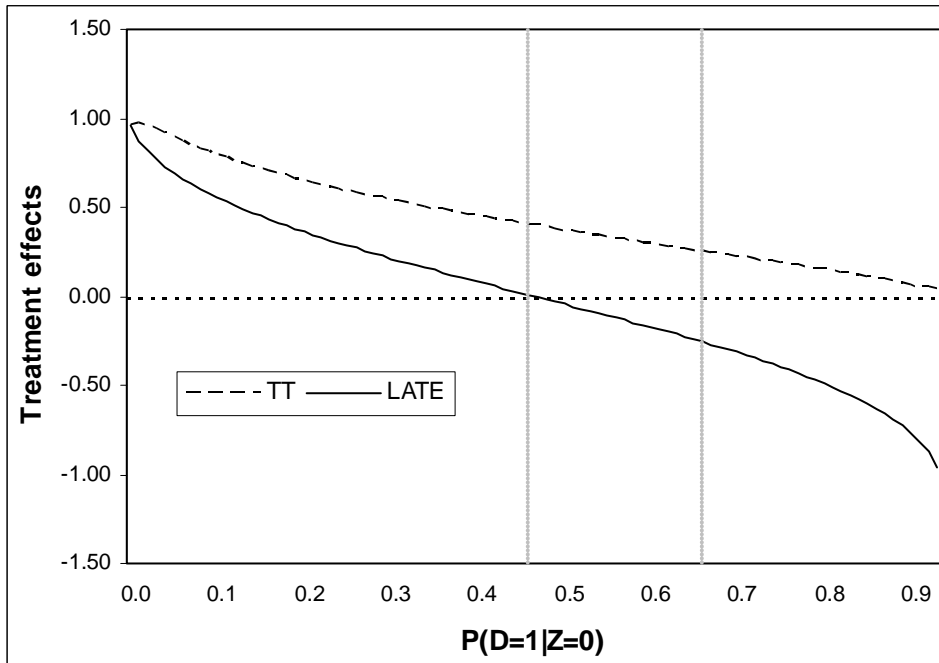

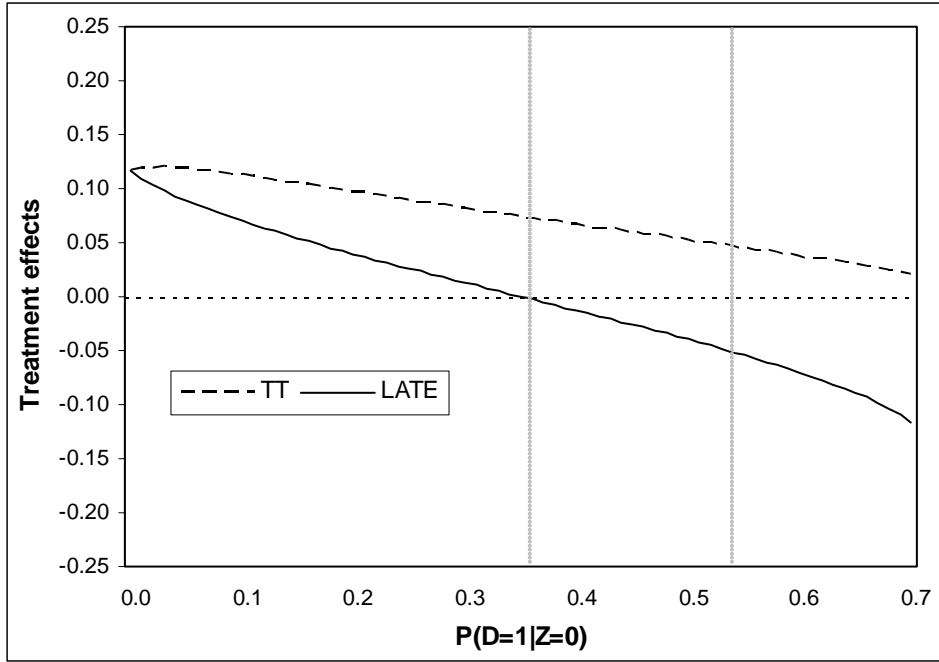

Figure 1: The relationship between LATE, ATE and the effect on the treated for alternative first-stage baseline values. The first-stage effect is fixed at .07 and $ATE=0$. The top panel calculation sets the correlation between gains and the treatment index to $-.1$, while the bottom panel sets this correlation to $-.5$.

Panel A: Moderate selection on gains

Panel B: Strong selection on gains

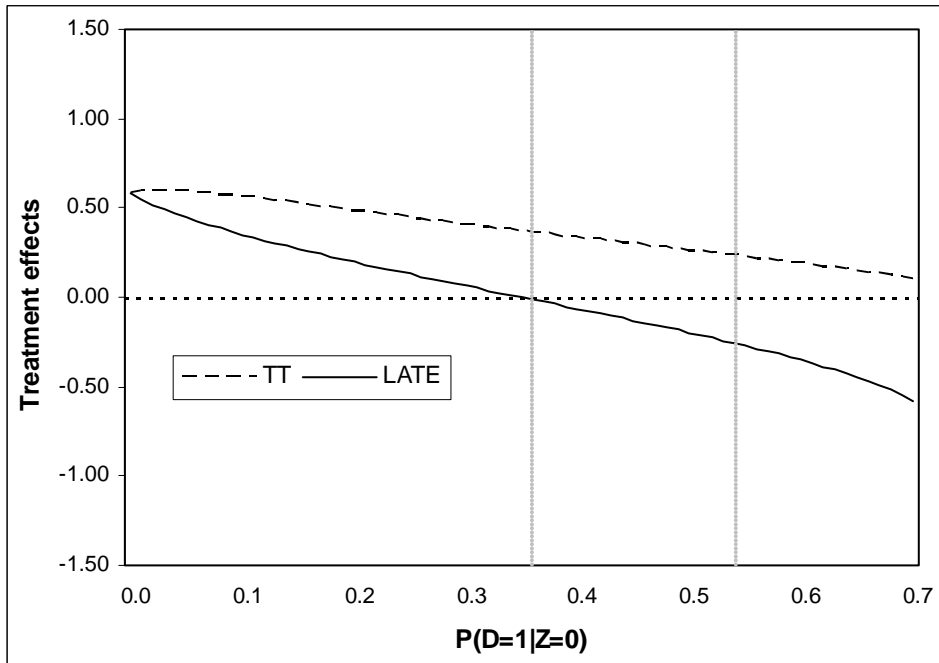

Figure 2: The relationship between LATE, ATE and the effect on the treated for alternative first-stage baseline values. The first-stage effect is fixed at .30 and $ATE=0$. The top panel calculation sets the correlation between gains and the treatment index to $-.1$, while the bottom panel sets this correlation to $-.5$.

Figure 3: Distribution of first-stage base probability as a function of covariates. The covariates are age, age at first birth, Black and Hispanic dummies, and dummies for some college and college graduates. There are about 1,700 values in the histogram.
